This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history,

laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Dedication

As we near the 50th anniversary of Applied Therapeutics, *the editors wish to honor Dr. Mary Anne Koda-Kimble and Dr. Lloyd Young who created* Applied Therapeutics, *the gold standard textbook used in the teaching of patient-centered drug therapeutics. Their vision and legendary contributions have advanced health professions education for generations of healthcare students who are making a difference in the lives of their patients and the communities in which they serve.*

After embarking on the twelfth edition of Applied Therapeutics, *the COVID-19 pandemic brought forward unexpected challenges to a dedicated team of over 200 contributors for this edition. Many of our contributors served in dual roles as health professions educators and as healthcare providers on the front lines managing the pandemic. We dedicate this twelfth edition to them, as well as the health professions students who demonstrated resilience to advance their education and training during the pandemic. Finally, we wish to thank our*

families for their patience and unwavering support as we navigated through the winding roads of this journey and completed this twelfth edition of the textbook.

Preface

Health professions education was significantly affected by the COVID-19 pandemic, as there was a significant need to adapt the delivery of clinical education. Many health professions programs redesigned curriculum to incorporate virtual educational tools with enhancements to online education. The pandemic has shown us more than ever the importance of educating students who are able to think critically and to utilize problem-solving skills to address healthcare challenges. Approximately five decades later, the founding principle for this textbook—a patient-centric, case-based approach to learning—remains the cornerstone of health professions education. Our authors present approximately 900 patient cases that stimulate the reader to integrate and apply therapeutic principles in the context of specific clinical situations. Health professions students and practitioners gain a glimpse into the minds of expert clinicians as they work to assess and solve therapeutic problems and develop their own critical thinking and problem-solving skills.

Readers familiar with past editions of the book will notice that the overall design of the book is consistent with the eleventh edition, which incorporates a Core Principles section at the beginning of each chapter, providing the most important “take home” information from the chapter. Each Core Principle is mapped to specific cases within the chapter where the principle is discussed in detail. Key references and websites are listed at the end of each chapter, whereas the full reference lists for each chapter have been moved online.

Building upon the excellent foundation of case-based learning provided in previous editions, the twelfth edition has incorporated changes to meet the evolving educational needs of health professions educators and students across the globe. The editors and contributors have utilized the five Institute of Medicine (IOM) core competencies as a broad framework for proposing case studies and questions within the textbook: patient-centered care, interprofessional teams, evidence-based practice, quality improvement, and informatics. In addition, the Accreditation Council for Pharmacy Education (ACPE) Accreditation Standards 2016, the Center for the Advancement of Pharmacy Education (CAPE) Educational Outcomes, and the North American Pharmacist Licensure Examination (NAPLEX) revised competency statements have served as road maps for the editorial team and contributors in designing the twelfth edition.

Featuring contributions from more than 200 experienced health professions educators, every chapter has been revised and updated to reflect our ever-changing knowledge of drugs and the application of this knowledge to the individualized therapy of patients. Given the importance of incorporating Interprofessional Practice and Education (IPE) within health professions curricula, we have dedicated a chapter on IPE, as well as an array of IPE case studies prepared by contributors that are representative of various sections of the textbook. These IPE cases, along with answer guides, will be available for instructors on the textbook's website (see the "Additional Resources" section).

We welcome your feedback as we undertake planning for the next edition. The authors have drawn on information from the literature, current standards, and their own clinical experiences to share the process involved in making sound and thoughtful therapeutic decisions. *However, it remains the responsibility of every practitioner to evaluate the appropriateness of a particular opinion in the context of the actual clinical situation, bearing in mind any recent developments in the field. We strongly urge students and practitioners to consult several appropriate information sources when working with new and unfamiliar drugs*.

A L G r a w a n y

Acknowledgments

We are deeply indebted to the many dedicated people who have given of themselves to complete the twelfth edition of *Applied Therapeutics: The Clinical Use of Drugs*. We are grateful to our contributing authors who have worked tirelessly and with resolve to provide the highest quality of work, while providing vital services to patients during the pandemic, along with numerous responsibilities as educators, clinicians, and researchers. We are grateful for the exceptional work of our 28 section editors, who provided critical feedback necessary both in the organizational structure of the textbook and in the individual editing of chapters; without their dedication and support, this edition would not have been possible. We sincerely thank the past editorial team of *Applied Therapeutics*, with special thanks to Dr. B. Joseph Guglielmo for his guidance and support and contributions to this textbook.

The team from Wolters Kluwer, Matt Hauber, Deborah Bordeaux, Kelly Horvath, Venugopal Loganathan, Sean Hanrahan, and Susan Thomas, deserves special recognition for their efforts. Their exceptional patience, attention to detail, and guidance have been critical to the success of this project. We sincerely thank Catherine Ott (project management) and Subhash Nataraj (production) for their assistance in completing this edition. Most importantly, we wish to acknowledge the love, understanding, and unwavering support of our spouses and families. They selflessly gave to us early mornings, late nights, weekends, and vacation time that we spent writing and editing.

Consistent with past editions, we continue to dedicate our work to our students who inspire us and to the many patients we have been privileged to care for and who have taught us invaluable lessons. We also dedicate the twelfth edition to those health professions educators and clinicians who have served as pioneering leaders and role models in the delivery of patient-centered care using team-based approaches.

Additional Resources

The twelfth edition of *Applied Therapeutics: The Clinical Use of Drugs* includes additional resources for both instructors and students, available on the book's companion website at **http://thepoint.lww.com/AT12e**.

STUDENT RESOURCES

Students who have purchased *Applied Therapeutics: The Clinical Use of Drugs*, Twelfth Edition, have access to the following additional resources for each chapter:

- A full online reference list for that chapter

INSTRUCTOR RESOURCES

Approved adopting instructors will be given access to the following additional resources:

- Interprofessional Education (IPE) Case Studies and Answer Guides
- Each chapter will map which NAPLEX competency statements are addressed within it, which will be a helpful resource for instructors.

Department of Pharmacy
Faculty of Science
National University of Singapore
Singapore, Singapore

Molly E. Howard, PharmD, BCPS, BCACP

Clinical Pharmacy Specialist—Primary Care
VA VISN 7 Clinical Resource Hub
PGY1 Residency Program Director
Central Alabama Veterans Health Care System
Montgomery VA Clinic
Montgomery, Alabama

Timothy R. Hudd, BS, PharmD, AE-C

Professor of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Rupali Jain, PharmD

Clinical Associate Professor
Department of Pharmacy
University of Washington
Seattle, Washington

Steven W. Johnson, PharmD, CPP, AAHIVP

Associate Professor
Department of Pharmacy Practice
Campbell University College of Pharmacy and Health Sciences
Winston-Salem, North Carolina

Donyika Joseph, PharmD

Clinical Pharmacy Specialist
Department of Pharmacy

The University of Texas MD Anderson Cancer Center
Houston, Texas

Nicole A. Kaiser, BS Pharmacy

Clinical Pharmacy Specialist
Department of Pharmacy
Children's Hospital Colorado
Aurora, Colorado

James S. Kalus, PharmD

Director of Pharmacy
Department of Pharmacy Services
Henry Ford Health
Detroit, Michigan

Amy Kang, PharmD

Assistant Professor
Department of Pharmacy Practice
Chapman University School of Pharmacy
Harry and Diane Rinker Health Science Campus
Irvine, California
Infectious Diseases Pharmacist
Department of Pharmacy
Harbor-UCLA Medical Centre
Torrance, California

Neha Kashalikar, PharmD

Clinical Pharmacist
Office of Clinical Affairs, Commonwealth Medicine
University of Massachusetts Chan Medical School
Quincy, Massachusetts

Marina D. Kaymakcalan, PharmD, BCOP

Genitourinary Clinical Pharmacy Specialist & Oral Anticancer Education Manager
Department of Pharmacy
Dana-Farber Cancer Institute

Boston, Massachusetts

Michael B. Kays, PharmD, FCCP, BCIDP
Associate Professor
Department of Pharmacy Practice
Purdue University College of Pharmacy
Indianapolis, Indiana

Jacob K. Kettle, PharmD
Director—Ellis Fischel Cancer Center
University of Missouri Health Care
Columbia, Missouri

Steven S. Kheloussi, PharmD, MBA
Assistant Professor of Pharmacy Practice
Department of Pharmacy Practice
Nesbitt School of Pharmacy
Wilkes University
Wilkes-Barre, Pennsylvania

Hyun Kim, PharmD
Clinical Pharmacist
Clinical Pharmacogenomics Service
Department of Pharmacy
Boston Children's Hospital
Boston, Massachusetts

Abigail Klutts, PharmD
Clinical Pharmacy Specialist, Ambulatory Care Pharmacy
The Johns Hopkins Hospital
Baltimore, Maryland

Mary P. Kovacevic, PharmD, BCCCP, BCPS
Clinical Pharmacy Specialist
Department of Pharmacy

Brigham and Women's Hospital
Boston, Massachusetts

Lee A. Kral, PharmD, CPE

Clinical Assistant Professor
Anesthesia Department
University of Iowa Carver College of Medicine
Iowa City, Iowa

Susan A. Krikorian, MS, PharmD

Professor Emerita of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Jerika T. Lam, PharmD, AAHIVP, FCSHP

Associate Professor of Pharmacy Practice
Chapman University School of Pharmacy
Irvine, California

Trisha LaPointe, PharmD, BCPS, FASHP

Professor of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Alan H. Lau, PharmD

Professor of Pharmacy Practice
University of Illinois at Chicago
Chicago, Illinois

Elaine J. Law, PharmD, BCPS, FCSHP

Associate Clinical Professor
Department of Pharmacy Practice
University of the Pacific Thomas J. Long School of Pharmacy

Stockton, California

Kimberly Lenz, PharmD, MBA
Senior Pharmacy Director
Office of Clinical Affairs, Commonwealth Medicine
University of Massachusetts Chan Medical School
Quincy, Massachusetts

Russell E. Lewis, PharmD
Associate Professor of Medicine, Infectious Diseases
Department of Medical and Surgical Sciences
University of Bologna
Bologna, Italy

Troy Lynn Lewis, PharmD
Assistant Professor of Pharmacy Practice
Nesbitt School of Pharmacy
Wilkes University
Wilkes-Barre, Pennsylvania

Rachel C. Long, PharmD, BCPS, CPP, CDCES
Ambulatory Care Pharmacist Pharmacy
Atrium Health
Charlotte, North Carolina

Ann M. Lynch, PharmD, RPh, AE-C
Professor of Pharmacy Practice
School of Pharmacy—Worcester
Massachusetts College of Pharmacy and Health Sciences
Worcester, Massachusetts

Matthew R. Machado, PharmD
Professor of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences

Boston, Massachusetts

Daniel R. Malcom, PharmD, BCPS, BCCCP
Associate Professor and Chair
Department of Pharmacy Practice
Sullivan University College of Pharmacy and Health Sciences
Louisville, Kentucky

Shannon F. Manzi, PharmD
Director, Safety & Quality
Assistant Professor of Pediatrics
Department of Pharmacy
Boston Children's Hospital, Harvard Medical School
Boston, Massachusetts

Kathleen Marquis, PharmD, PhD
Clinical Pharmacist
Department of Pharmacy
Brigham and Women's Hospital
Boston, Massachusetts

Joel C. Marrs, PharmD, MPH
Clinical Associate Professor
Pediatrics and Child Health Associate/Physician Assistant Program
University of Colorado School of Medicine
Aurora, Colorado
Ambulatory Pharmacy Clinical Coordinator
Department of Pharmacy
Billings Clinic
Billings, Montana

John Marshall, PharmD, BCPS, BCCCP, FCCM
Vice President, Clinical Pharmacy Services
Department of Pharmacy
Beth Israel Lahey Health
Westwood, Massachusetts

Shedrick Martin, PharmD, BCPP

Clinical Pharmacist Specialist
Department of Pharmacy
Santa Rosa Memorial Hospital
Santa Rosa, California

Susan L. Mayhew, PharmD

Dean and Professor
Pharmacy Practice
Appalachian College of Pharmacy
Oakwood, Virginia

Sarah E. McBane, PharmD, BCPS, FCCP, FCPhA, FSCHP, APh

Founding Associate Dean of Pharmacy Education
Department of Clinical Pharmacy Practice
UCI School of Pharmacy and Pharmaceutical Sciences
Irvine, California

Chephra McKee, PharmD

Clinical Pharmacy Specialist, NICU
UT Southwestern Medical Center
Dallas, Texas

Mary Mihalyo, BS, PharmD, BCPS

Assistant Professor
Department of Clinical Pharmacy Practice
Duquesne University Mylan School of Pharmacy
Pittsburgh, Pennsylvania

Emi Minejima, PharmD

Associate Professor
Department of Clinical Pharmacy
University of Southern California School of Pharmacy
Los Angeles, California

Molly G. Minze, PharmD, FCCP, BCACP

Associate Professor of Pharmacy Practice
Associate Dean of Student Affairs & Admissions
Department of Pharmacy Practice
Jerry H. Hodge School of Pharmacy
Texas Tech University Health Sciences Centre
Abilene, Texas

Amee Mistry, PharmD

Professor of Pharmacy Practice
Director, Biopharmaceutical Industry Fellowship Program
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Anna K. Morin, PharmD

Associate Provost Worcester/Manchester and Professor of Pharmacy Practice
Academic Affairs
Massachusetts College of Pharmacy and Health Sciences
Worcester, Massachusetts

Pamela Morris, MD

Professor of Medicine
Medical University of South Carolina
Charleston, South Carolina

Oussayma Moukhachen, PharmD, BCPS, BCCCP

Associate Professor of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Kelly A. Mullican, PharmD, BCACP

Clinical Pharmacy Coordinator
Department of Pharmacy

Kaiser Permanente Mid-Atlantic States
Washington, District of Columbia

Margaret K. Murphy, PharmD

Clinical Pharmacist, GI/Nutrition
Department of Pharmacy
Boston Children's Hospital
Boston, Massachusetts

Yulia A. Murray, PharmD

Associate Professor of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Victoria Nachar, PharmD, BCOP

Clinical Pharmacist Specialist, Ambulatory Hematology
Department of Pharmacy
University of Michigan Rogel Cancer Center
Ann Arbor, Michigan

Milap C. Nahata, MS, PharmD, FCCP, FASHP, FAPhA, FPPA

Director, Institute of Therapeutic Innovations and Outcomes
Professor Emeritus of Pharmacy, Pediatrics and Internal Medicine
Colleges of Pharmacy and Medicine
The Ohio State University
Columbus, Ohio

Matthew Newman, PharmD, MEHP, BCOP

Clinical Pharmacist Practitioner, Hematologic Malignancies
Department of Pharmacy
The Johns Hopkins Hospital
Baltimore, Maryland

Kimmy Nguyen, PharmD
Assistant Professor
Department of Pharmacy Practice
Wilkes University
Wilkes-Barre, Pennsylvania

Richard S. Nicholas, PharmD, ND
Chair, Department of Pharmacy Practice
Appalachian College of Pharmacy
Oakwood, Virginia

Samar E. Nicolas, PharmD
Assistant Professor of Pharmacy Practice
School of Pharmacy—Worcester
Massachusetts College of Pharmacy and Health Sciences
Worcester, Massachusetts

Stefanie C. Nigro, PharmD
Associate Clinical Professor
Department of Pharmacy Practice
University of Connecticut
Storrs, Connecticut

Cindy L. O'Bryant, PharmD, BCOP, FCCP, FHOPA
Professor
Associate Dean of Academic and Faculty Affairs
Department of Clinical Pharmacy
Skaggs School of Pharmacy and Pharmaceutical Sciences
University of Colorado—Anschutz Medical Campus
Aurora, Colorado

Kirsten H. Ohler, PharmD, FCCP, BCPS, BCPPS
Clinical Associate Professor of Pharmacy Practice
College of Pharmacy
University of Illinois at Chicago

Clinical Pharmacy Specialist
Neonatal ICU
University of Illinois Chicago Hospital & Health Sciences System
Chicago, Illinois

Julie L. Olenak, PharmD

Associate Dean/Professor
Nesbitt School of Pharmacy
Wilkes University
Wilkes-Barre, Pennsylvania

Jacqueline L. Olin, MS, PharmD

Scientific Director
Clinical Education Alliance
Reston, Virginia

Neeta Bahal O'Mara, PharmD, BCPS

Clinical Pharmacist
Dialysis Clinic, Inc.
North Brunswick, New Jersey

Nicole E. Omecene, PharmD, BCPPS

Assistant Professor
Pharmacotherapy and Outcomes Science
Virginia Commonwealth University
Richmond, Virginia

Stephanie M. Ozalas, PharmD, BCPS, BCGP

Clinical Assistant Professor and Geriatrics
Clinical Pharmacy Specialist
University of Maryland School of Pharmacy and VA Maryland Health Care System
University of Maryland, Baltimore
Baltimore, Maryland

Robert Lee Page II, PharmD, MSPH

Professor of Clinical Pharmacy, Medicine, and Physical Medicine
University of Colorado Schools of Pharmacy and Medicine
Aurora, Colorado

Louise Parent-Stevens, PharmD, BCPS

Forest Park, Illinois

Jaini Patel, PharmD, BCACP

Associate Professor
Clinical Pharmacist, Advocate Medical Group Chronic Disease Management
Department of Pharmacy Practice
Midwestern University College of Pharmacy, Downers Grove Campus (CPDG)
Downers Grove, Illinois

Jennifer T. Pham, PharmD, BCPS, BCPPS

Clinical Associate Professor, Clinical Pharmacist—Neonatal/Pediatrics
Department of Pharmacy Practice
University of Illinois at Chicago, College of Pharmacy
Chicago, Illinois

Jonathan Picker, MBChB, PhD

Clinical Geneticist, Director of Pharmacogenomic Service
Assistant Professor in Genetics
Department of Genetics
Boston Children’s Hospital, Harvard Medical School
Boston, Massachusetts

Nicole A. Pilch, PharmD, MSCR, CPHQ, BCPS, FAST

Professor
Department of Pharmacy and Clinical Sciences
Medical University of South Carolina
Charleston, South Carolina

David J. Quan, PharmD, BCPS

Pharmacist Specialist—Solid Organ Transplant
Department of Pharmaceutical Services
UCSF Medical Centre
Health Sciences Clinical Professor of Pharmacy
Department of Clinical Pharmacy
University of California San Francisco
San Francisco, California

Erin C. Raney, PharmD, FCCP, BCPS, BC-ADM

Professor
Department of Pharmacy Practice
Midwestern University College of Pharmacy—Glendale
Glendale, Arizona

Joshua Reardon, PharmD, BCOP

Oncology Specialty Pharmacist
Columbus Oncology Associates
Columbus, Ohio

Valerie Relias, PharmD, BCOP

Clinical Pharmacy Specialist
Assistant Professor of Medicine
Division of Hematology/Oncology
Tufts University School of Medicine
Boston, Massachusetts

Michelle M. Richardson, PharmD

Special and Scientific Staff
William B. Schwartz Division of Nephrology
Tufts Medical Center
Boston, Massachusetts

Charmaine Rochester-Eyeguokan, PharmD

Professor
Department of Pharmacy Practice and Science
University of Maryland School of Pharmacy

Baltimore, Maryland

Carol J. Rollins, MS, RD, PharmD
Clinical Professor
Pharmacy Practice and Science
The University of Arizona College of Pharmacy
Tucson, Arizona

Melody Ryan, PharmD, MPH
Professor
Department of Pharmacy Practice and Science
University of Kentucky College of Pharmacy
Lexington, Kentucky

Melissa Sandler, PharmD, BCCCP
Post-doc/Fellow
Department of Pharmacotherapy and Outcomes Science
Virginia Commonwealth University
Richmond, Virginia

Nikhil A. Sangave, PharmD, BCACP
Adjunct Assistant Professor of Pharmacy Practice
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

David Schnee, PharmD, BCACP
Professor and Vice Chair
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Eric F. Schneider, BS Pharmacy, PharmD
Vice Provost for Institutional Effectiveness
Office of the Provost
Wingate University

Wingate, North Carolina

Sheila M. Seed, PharmD, MPH, CTH, AFTM RCPS (Glasg), RPh

Professor and Chair of Pharmacy Practice
School of Pharmacy—Worcester
Massachusetts College of Pharmacy and Health Sciences
Worcester, Massachusetts

Nancy L. Shapiro, PharmD, FCCP, BCACP, CACP

Clinical Professor and Assistant Head for Education
Department of Pharmacy Practice
University of Illinois at Chicago College of Pharmacy
Clinical Pharmacist and Coordinator
Antithrombosis Clinic
UI Health
Chicago, Illinois

Iris Sheinhait, PharmD

Certified Poison Information Specialist
Pharmacology/Toxicology
Boston Children's Hospital
Boston, Massachusetts

Devon A. Sherwood, PharmD, BCPP

Associate Professor
Department of Pharmacy Practice
University of New England School of Pharmacy
Westbrook College of Health Professions
Portland, Maine

Richard J. Silvia, PharmD, BCPP

Professor of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences

Boston, Massachusetts

Divita Singh, PharmD
Clinical Assistant Professor
Department of Pharmacy Practice
Temple University School of Pharmacy
Philadelphia, Pennsylvania

Harleen Singh, PharmD
Clinical Professor
School of Pharmacy
University of Texas at El Paso
El Paso, Texas

Linda M. Spooner, PharmD
Professor of Pharmacy Practice
School of Pharmacy—Worcester
Massachusetts College of Pharmacy and Health Sciences
Worcester, Massachusetts

Karyn M. Sullivan, PharmD, MPH
Assistant Dean of IPE and Professor of Pharmacy Practice
School of Pharmacy—Worcester
Massachusetts College of Pharmacy and Health Sciences
Worcester, Massachusetts

Allison E. Symonds, PharmD
Postdoctoral Pharmacokinetics & Pharmacodynamics Fellow
Division of Pharmacotherapy and Experimental Therapeutics
University of North Carolina at Chapel Hill Eshelman School of Pharmacy
Chapel Hill, North Carolina

Kristen Szempruch, PharmD
Clinical Pharmacy Specialist—Inpatient Abdominal Transplant
Assistant Professor of Clinical Education—UNC Eshelman School of Pharmacy

Department of Pharmacy
University of North Carolina Medical Center
Chapel Hill, North Carolina

David J. Taber, PharmD, MS

Professor
Division of Transplant Surgery, Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

Kimberly Tallian, PharmD, APh, BCPP, FASHP, FCCP

Advanced Practice Pharmacist—Neuropsychiatry Pharmacy
Scripps Mercy Hospital, San Diego
San Diego, California

Yasar O. Tasnif, PharmD, BCPS, FAST

Associate Professor of Practice
School of Pharmacy
University of Texas at El Paso
El Paso, Texas

Kate Deen Taucher, PharmD, MHA, FASHP, BCOP

System Manager
Oncology & Infusion Pharmacy Services
UC Health
Aurora, Colorado

Daniel J. G. Thirion, PharmD, FCSHP

Full Clinical Professor
Pharmacist and Researcher
Faculty of Pharmacy
Department of Pharmacy
Universite de Montreal
McGill University Health Center

Montreal, Quebec, Canada

Angela M. Thompson, PharmD, BCPS
Senior Clinical Instructor
Skaggs School of Pharmacy and Pharmaceutical Sciences
University of Colorado—Anschutz Medical Campus
Aurora, Colorado

Lisa A. Thompson, PharmD, BCOP
Specialist in Oncology
Department of Clinical Pharmacy
Kaiser Permanente Colorado
Lafayette, Colorado

Ricky B. Thumar, PharmD, RPh
Assistant Professor of Pharmacy Practice
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Dominick P. Trombetta, PharmD, BCPS, BCGP, FASCP
Associate Professor
Department of Pharmacy Practice Geriatrics/Internal Medicine
Wilkes University
Wilkes-Barre, Pennsylvania

Toby C. Trujillo, PharmD, FCCP, FAHA, BCPS
Associate Professor
Skaggs School of Pharmacy and Pharmaceutical Sciences
University of Colorado—Anschutz Medical Campus
Clinical Specialist
Cochair, Anticoagulation Subcommittee UC Health
Anticoagulation/Cardiology
University of Colorado Hospital

Aurora, Colorado

Anne Walsh, PA-C, MMSc, DFAAPA

Clinical Associate Professor
PA Studies Program
Physician Assistant Studies
Crean College of Health and Behavioral Sciences
Chapman University
Irvine, California

Kaiwen Wang, PharmD

Clinical Pharmacy Specialist
Department of Pharmacy
The University of Texas MD Anderson Cancer Center
Houston, Texas

Sheila K. Wang, PharmD

Associate Professor of Pharmacy Practice
Department of Pharmacy Practice
Midwestern University College of Pharmacy
Downers Grove, Illinois

Ying Wang, PharmD

Assistant Professor of Clinical Pharmacy
Director, Professional Experience Programs
Supervisor, USC Safety-Net Clinical Pharmacy
Titus Family Department of Clinical Pharmacy
University of Southern California School of Pharmacy
Los Angeles, California

Kellie Jones Weddle, PharmD

Clinical Professor of Pharmacy Practice
Purdue University College of Pharmacy
Indianapolis, Indiana

C. Michael White, PharmD

Distinguished Professor
Department of Pharmacy Practice
University of Connecticut School of Pharmacy
Storrs, Connecticut

Barbara S. Wiggins, PharmD

Clinical Pharmacy Specialist—Cardiology Medicine
Department of Pharmacy Services
Medical University of South Carolina
Charleston, South Carolina

Kristine C. Willett, PharmD

Professor of Pharmacy Practice
School of Pharmacy—Manchester
Massachusetts College of Pharmacy and Health Sciences
Manchester, New Hampshire

Casey B. Williams, PharmD

Chief Scientific Officer and Executive Director of Cancer Research
Avera McKennan Hospital and University Health Center
Sioux Falls, South Dakota

Dennis M. Williams, PharmD

Associate Professor
Division of Pharmacotherapy and Experimental Therapeutics
UNC Eshelman School of Pharmacy
Chapel Hill, North Carolina

Adrian Wong, PharmD, MPH, FCCM, BCCCP

Adjunct Associate Professor
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Chelsea Wong, PharmD
Clinical Pharmacy Specialist
The University of Texas MD Anderson Cancer Center
Houston, Texas

Annie Wong-Beringer, PharmD
Professor of Pharmacy
Associate Dean for Research
Department of Clinical Pharmacy
University of Southern California School of Pharmacy
Los Angeles, California

Dinesh Yogaratnam, PharmD
Associate Professor of Pharmacy Practice
School of Pharmacy—Worcester
Massachusetts College of Pharmacy and Health Sciences
Worcester, Massachusetts

Kathy Zaiken, PharmD
Professor of Pharmacy Practice
Director, International Pharmacy Residency Program
School of Pharmacy—Boston
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Caroline S. Zeind, PharmD
Vice President for Academic Affairs/Provost
Professor of Pharmacy Practice
Academic Affairs
Massachusetts College of Pharmacy and Health Sciences
Boston, Massachusetts

Kristin M. Zimmerman, PharmD
Associate Professor
Department of Pharmacotherapy & Outcomes Sciences

Richmond, Virginia

Brief Table of Contents

Preface
Acknowledgments
Additional Resources
Section Editors
Contributors
Detailed Table of Contents

VOLUME ONE

SECTION 1: GENERAL PRINCIPLES

Section Editors: Mary G. Amato and Maria Kostka-Rokosz

1 Medication Therapy Management and Assessment of Therapy
Matthew R. Machado, Joseph W. Ferullo, and Amee Mistry

2 Interpretation of Clinical Laboratory Tests

Erika Felix-Getzik, Yulia A. Murray, and Stefanie C. Nigro

3 Drug Interactions
Michelle Ceresia, Caroline S. Zeind, John Fanikos, and Michael G. Carvalho

4 Pharmacogenomics and Personalized Medicine
Hyun Kim, Shannon F. Manzi, Laura Chadwick, and Jonathan Picker

5 Managing Drug Overdoses and Poisonings
Iris Sheinhait

6 End-of-Life Care
Victoria F. Ferraresi and Mary Mihalyo

7 Interprofessional Practice and Education
Michael G. Carvalho, Edith Claros, Christopher K. Cooper, and Kaelen C. Dunican

SECTION 2: CARDIAC AND VASCULAR DISORDERS

Section Editors: Judy W. Cheng and Snehal H. Bhatt

8 Dyslipidemias, Atherosclerosis, and Coronary Heart Disease

Barbara S. Wiggins and Pamela Morris

9 Essential Hypertension
Judy W. Cheng

10 Peripheral Vascular Disorders
Snehal H. Bhatt

11 Thrombosis
Nancy L. Shapiro and Erika L. Hellenbart

12 Chronic Stable Angina
Angela M. Thompson and Toby C. Trujillo

13 Acute Coronary Syndrome
Brianne Dunn and Robert Lee Page II

14 Heart Failure
Harleen Singh and Joel C. Marrs

15 Cardiac Arrhythmias
C. Michael White and James S. Kalus

16 Hypertensive Crises
Sandeep Devabhakthuni, Ryan G. D'Angelo, and Michael Armahizer

17 Shock

Jason S. Haney and Carolyn M. Bell

SECTION 3: PULMONARY DISORDERS

Section Editors: Timothy R. Hudd and Kathy Zaiken

18 Asthma
Cary R. Chrisman and Christopher K. Finch

19 Chronic Obstructive Pulmonary Disease
Timothy R. Hudd and Kathy Zaiken

20 Acute and Chronic Rhinitis
Suzanne Bollmeier and Dennis M. Williams

21 Cystic Fibrosis
Paul M. Beringer and Michelle Condren

SECTION 4: GASTROINTESTINAL DISORDERS

Section Editor: Carrie A. Sincak

22 Nausea and Vomiting
Lisa M. DiGrazia and J. Todd Carter

23 Upper Gastrointestinal Disorders
Elaine J. Law and Ricky B. Thumar

24 Lower Gastrointestinal Disorders

Charmaine Rochester-Eyeguokan, Divita Singh, and Abigail Klutts

25 Complications of End-Stage Liver Disease
Yasar O. Tasnif and Mary F. Hebert

SECTION 5: RENAL DISORDERS

Section Editors: Susan A. Krikorian and Oussayma Moukhachen

26 Acid–Base Disturbances
Mary P. Kovacevic, Jeremy R. DeGrado, and Kevin E. Anger

27 Fluid and Electrolyte Disorders
Priscilla P. How and Alan H. Lau

28 Chronic Kidney Disease
Adinoyi Garba

29 Acute Kidney Injury
Susan A. Krikorian, Oussayma Moukhachen, and Alexander H. Flannery

30 Dialysis Treatment for Chronic Kidney Failure
Michelle M. Richardson

31 Dosing of Drugs in Kidney Failure

David J. Quan

SECTION 6: IMMUNOLOGIC DISORDERS

Section Editor: Steven Gabardi

32 Drug Hypersensitivity Reactions
Mariana C. Castells, Kathleen Marquis, and Kylie Marie Besz

33 Systemic Lupus Erythematosus
Jerika T. Lam, Ann M. Lynch, and Mary A. Gutierrez

34 Kidney and Liver Transplantation
David J. Taber, Robert E. Dupuis, Nicole A. Pilch, and Kristen Szempruch

SECTION 7: NUTRITION ISSUES

Section Editors: R. Rebecca Couris and Susan L. Mayhew

35 Basics of Nutrition and Patient Assessment
Margaret K. Murphy, Leigh Furman, and Kathleen M. Gura

36 Obesity
Kaelen C. Dunican and Aimee Dawson

37 Adult Enteral Nutrition
Carol J. Rollins

38 Adult Parenteral Nutrition
Susan L. Mayhew and Richard S. Nicholas

SECTION 8: DERMATOLOGIC DISORDERS

Section Editor: Katie Kiser

39 Dermatotherapy and Drug-Induced Skin Disorders
Daniel R. Malcom and Lynn Z. Fuller

40 Acne
Jamie J. Cavanaugh and Kelly A. Mullican

41 Psoriasis
Rachel C. Long and Kelly A. Mullican

42 Photosensitivity, Photoaging, and Burn Injuries
Molly E. Howard

SECTION 9: RHEUMATIC AND MUSCULOSKELETAL DISEASES

Section Editor: Kamala M. Nola

43 Osteoarthritis

Dominick P. Trombetta and Christopher M. Herndon

44 Rheumatoid Arthritis
Janet S. Cho and Ying Wang

45 Gout and Hyperuricemia
Troy Lynn Lewis and Kimmy Nguyen

46 Connective Tissue Disorders
Steven S. Kheloussi, Julie L. Olenak, and Jonathan D. Ference

SECTION 10: WOMEN'S HEALTH

Section Editor: Trisha LaPointe

47 Contraception
Shareen El-Ibiary

48 Infertility
Erin C. Raney

49 Obstetric Drug Therapy
Trisha LaPointe

50 Disorders Related to the Menstrual Cycle
Laura M. Borgelt and Karen M. Gunning

51 The Transition Through Menopause
Louise Parent-Stevens and Trisha LaPointe

SECTION 11: ENDOCRINE DISORDERS

Section Editors: Jennifer D. Goldman and David Schnee

52 Thyroid Disorders
Eric F. Schneider and Kamaria K. Brown

53 Diabetes Mellitus
Jennifer D. Goldman, Nikhil A. Sangave, and David Schnee

VOLUME TWO

SECTION 12: EYE DISORDERS

Section Editor: Susan Jacobson

54 Eye Disorders
Katherine Carey and Bridget C. Hendricks

SECTION 13: NEUROLOGIC DISORDERS

ALGrawany

Section Editors: Michele Matthews and Adrian Wong

55 Pain and Its Management
Virginia Ghafoor, Lee A. Kral, and Timothy J. Atkinson

56 Care of the Critically Ill Adult
Philip Grgurich, Adrian Wong, and John Marshall

57 Multiple Sclerosis
Melody Ryan

58 Headache
Steven J. Crosby

59 Parkinson Disease and Other Movement Disorders
Shedrick Martin and Kimberly Tallian

60 Seizure Disorders
Sulaiman Almohaish, Melissa Sandler, Nicole E. Omecene, and Gretchen M. Brophy

61 Acute Ischemic and Hemorrhagic Stroke
Oussayma Moukhachen and Philip Grgurich

SECTION 14: INFECTIOUS DISEASES

Section Editors: Dorothea Rudorf, G. Christopher Wood, and Caroline S. Zeind

62 Principles of Infectious Diseases
Joshua A. Garcia and B. Joseph Guglielmo

63 Antimicrobial Prophylaxis for Surgical Procedures
Daniel J. G. Thirion

64 Vaccinations
Molly G. Minze and Katie D. Ellis

65 Central Nervous System Infections
Deanna J. Buehrle and Gregory A. Eschenauer

66 Endocarditis
Annie Wong-Beringer, Rachid Douglas-Louis, and Emi Minejima

67 Respiratory Tract Infections
Jason Cross, Evan Horton, and Dinesh Yogaratnam

68 Tuberculosis
Michael B. Kays

69 Infectious Diarrhea
Rupali Jain and David T. Bearden

70 Intra-Abdominal Infections
Christie M. Bertram and Sheila K. Wang

71 Urinary Tract Infections
Douglas N. Fish

72 Sexually Transmitted Diseases
Albert Bach, Anne Walsh, and Karl M. Hess

73 Osteomyelitis and Septic Arthritis
Jacqueline L. Olin, Linda M. Spooner, and Karyn M. Sullivan

74 Skin and Soft Tissue Infections
Cheryl R. Durand and Kristine C. Willett

75 Prevention and Treatment of Infections in Neutropenic Cancer Patients
Richard H. Drew and Steven W. Johnson

76 Pharmacotherapy of Human Immunodeficiency Virus Infection
Aaron S. Devanathan, Allison E. Symonds, Jessica L. Adams, and Mackenzie L. Cottrell

77 Opportunistic Infections in Patients Living With HIV
Emily L. Heil and Amanda H. Corbett

78 Fungal Infections
John Cleary and Russell E. Lewis

79 Viral Infections
Sandra Benavides, Neeta Bahal O'Mara, and Milap C. Nahata

80 Viral Hepatitis
Jerika T. Lam and Amy Kang

81 Parasitic Infections
Sheila M. Seed, Janelle I. Herren, Samar E. Nicolas, Larry Goodyer, and Caroline S. Zeind

82 Tick-Borne Diseases
Caroline S. Zeind, Michelle Ceresia, and Lin H. Chen

SECTION 15: PSYCHIATRIC DISORDERS AND SUBSTANCE ABUSE

Section Editors: Michael C. Angelini and Michael G. Carvalho

83 Anxiety Disorders
Tamara Bystrak and Amanda Eloma

84 Sleep Disorders
Devon A. Sherwood and Anna K. Morin

85 Schizophrenia
Richard J. Silvia, Robert L. Dufresne, and Justin C. Ellison

86 Depressive Disorders
Michael C. Angelini

87 Bipolar Disorders
Megan J. Ehret and Charles F. Caley

88 Developmental Disorders
Kimberly Lenz and Neha Kashalikar

89 Attention-Deficit Hyperactivity Disorder in Children, Adolescents, and Adults
Michael C. Angelini and Joel Goldstein

90 Substance Use Disorders
Swati Betharia and Michael C. Angelini

91 Tobacco Use and Dependence
Andrea S. Franks and Sarah E. McBane

SECTION 16: HEMATOLOGY AND ONCOLOGY

Section Editor: Christy S. Harris

92 Anemias
Cindy L. O'Bryant, Kate Deen Taucher, and Lisa A. Thompson

93 Neoplastic Disorders and Their Treatment: General Principles
Michael Frei, Donyika Joseph, Kaiwen Wang, and Chelsea Wong

94 Adverse Effects of Chemotherapy, Immunotherapy, and Targeted Agents
Victoria Nachar and Matthew Newman

95 Pediatric Malignancies
M. Brooke Bernhardt and Nicole A. Kaiser

96 Adult Hematologic Malignancies
Casey B. Williams, Rachel Elsey, Sarah M. Hayes, and Jacob K. Kettle

97 Breast Cancer
Kellie Jones Weddle

98 Lung Cancer

Maryann R. Cooper

99 Colorectal Cancer
Marlo Blazer and Joshua Reardon

100 Prostate Cancer
Marina D. Kaymakcalan and Christy S. Harris

101 Hematopoietic Stem Cell Transplantation
Valerie Relias

SECTION 17: PEDIATRICS

Section Editor: Elizabeth Anne Farrington

102 Pediatric Pharmacotherapy
Elizabeth Anne Farrington

103 Pediatric Fluid, Electrolytes, and Nutrition
Jennifer W. Chow and Lisa M. Feagin

104 Common Pediatric Illnesses
Chephra McKee and Gildon Brooke

105 Neonatal Therapy
Jennifer T. Pham and Kirsten H. Ohler

106 Care of the Critically Ill Child

Elizabeth Anne Farrington

SECTION 18: GERIATRIC THERAPY

Section Editor: Judith L. Beizer

107 Geriatric Drug Use
Suzanne Dinsmore, Mary-Kathleen Grams, and Kristin M. Zimmerman

108 Geriatric Neurocognitive Disorders
Nicole J. Brandt and Stephanie M. Ozalas

109 Geriatric Urologic Disorders
Jaini Patel

110 Osteoporosis
Mary-Kathleen Grams, R. Rebecca Couris, and Suzanne Dinsmore

Contributors
Brief Table of Contents

VOLUME ONE

SECTION 1: GENERAL PRINCIPLES

Section Editors: *Mary G. Amato* and Maria Kostka-Rokosz

1 Medication Therapy Management and Assessment of Therapy
Matthew R. Machado, Joseph W. Ferullo, and Amee Mistry

Introduction
Sources of Patient Information

Effective Communication and the Patient Interview
Obtaining a Patient History
Approach to and Assessment of Patient Therapy
Medication Therapy Management Services in the Community Pharmacy or Ambulatory Setting
Medication Therapy Management in the Acute Care Setting
Medication Therapy Management and Pharmacogenomics
Conclusion
Acknowledgments
Key References and Websites

2 Interpretation of Clinical Laboratory Tests
Erika Felix-Getzik, Yulia A. Murray, and Stefanie C. Nigro

Introduction
General Principles
Fluids and Electrolytes
Multichemistry Panels
Proteins
Cardiac Markers
Liver Function Tests
Miscellaneous Tests
Hematology
Urinalysis
Therapeutic Drug Monitoring
Patient-Directed Monitoring and Testing
Key References and Websites

3 Drug Interactions

ALGrawany

Michelle Ceresia, Caroline S. Zeind, John Fanikos, and Michael G. Carvalho

Introduction
Definition
Risk Factors for Drug Interactions
Mechanisms of Drug Interactions
Management of Drug Interactions
Resources and Evidence for Clinical Decision Support
Conclusion
Key References and Websites

4 Pharmacogenomics and Personalized Medicine
Hyun Kim, Shannon F. Manzi, Laura Chadwick, and Jonathan Picker

Introduction
Pharmacokinetic Implications
Pharmacodynamic Implications
Implications in Acute Toxicity
Drug Target Implications
Nonmetabolic Implications
CYP2D6 Peculiarities
Impact of Pediatric Enzyme Development on Pharmacogenomics
Familial Implications of Pharmacogenetics
Making the Case for Pharmacogenomics
Conclusion
Key References and Websites

5 Managing Drug Overdoses and Poisonings
Iris Sheinhait

Introduction
General Management

1

Medication Therapy Management and Assessment of Therapy

Matthew R. Machado, Joseph W. Ferullo, and Amee Mistry

CORE PRINCIPLES		CHAPTER CASES
1	Medication therapy management services (MTMS) are a service or group of services that optimize therapeutic outcomes for individual patients.	**Case 1-4 (Questions 1–4)**
2	A successful MTMS encounter includes medication reconciliation and a comprehensive medication history.	**Case 1-1 (Questions 1–3)**
3	Sources of patient information for MTMS include the patient, the electronic health record, the paper chart, and the pharmacy information system.	**Case 1-4 (Questions 1, 5), Table 1-1**
4	A careful and complete patient interview should include medical, medication, and	**Case 1-1 (Questions 1–3), Table 1-2, Online Content**

	social histories, and must be provided in a culturally sensitive manner.	
5	A successful MTMS encounter must be well documented following the problem-oriented medical record (POMR). Documentation involves collecting subjective and objective data to identify the primary problem.	**Case 1-2 (Question 1)** **Case 1-3 (Question 1)** **Case 1-4 (Question 1), Table 1-4**
6	The clinician must assess the drug therapy or disease-specific problem and create a treatment plan.	**Case 1-4 (Questions 1, 2)**
7	The final step in documenting the MTMS encounter is developing the medication action plan and processing any billing requirements.	**Case 1-4 (Questions 1, 2, 4)**
8	Accurate and complete communication of the MTMS encounter to the patient's health care team is vital.	**Case 1-4 (Question 3)**

INTRODUCTION

This chapter discusses medication therapy management services (MTMS) with a focus on the assessment of drug therapy. The illustrations in this chapter primarily focus on the pharmacist; however, the principles used to assess patient response to drug therapy are of value to all health care providers.

As defined by the American Pharmacists Association (APhA), *medication therapy management (MTM)* is a term used to describe a broad range of health care services provided by pharmacists, the medication experts on the health care team. A consensus definition created by 11 national pharmacy associations, adopted by the

pharmacy profession in 2004, defines MTM as a service or group of services that optimize therapeutic outcomes for individual patients.[1] Pharmacists provide MTM to help patients get the best benefits from their medications by actively managing drug therapy and identifying, preventing, and resolving medication-related problems.

When practiced in the outpatient setting, MTMS can be used to assess patient adherence to medications, identify potential drug duplications, and provide an overall counseling service for medication therapy. MTM allows pharmacists to decrease medication-related errors while also educating patients on their medication regimens. A pharmacist plays a vital role in a patient's therapy management and can help relay information to a physician. During MTMS services, a pharmacist has the opportunity to confirm the potential use and appropriateness of medication in relation to a specific disease state. The Pharmacists Patient Care Process (PPCP) may be utilized in such instances. The process's five steps include collect, assess, plan, implement, and follow-up: monitor and evaluate. By utilizing the PPCP tool, a pharmacist can provide well-rounded care to each individual based on their specific conditions and needs.[2]

MTMS provide a significant opportunity to optimize drug regimens and create patient-centered care. The utilization of such services is crucial to a pharmacist's role in the health care system. In addition to the therapeutic outcome benefits, there is the potential for a considerable financial benefit from conducting MTMS because these services are primarily focused on patients with multiple chronic conditions, which can pose a significant burden on our health care system. According to a study evaluating MTMS, it was observed that a 31% reduction in total health care expenditures occurred, resulting in a 12:1 savings to cost ratio.[2] Therefore, MTMS are a valuable tool that all pharmacists should utilize when necessary because they can provide a great therapeutic benefit and a potential reduction in health care costs.

MTM has a direct relationship to pharmaceutical care. Pharmaceutical care has been described as *the responsible provision of drug therapy to achieve definite outcomes that are*

intended to improve a patient's quality of life.[3,4] In fact, MTM has been described as a service provided in the practice of pharmaceutical care.[5] However, unlike pharmaceutical care, MTM is recognized by payers, has current procedural terminology (CPT) codes specifically for pharmacists, and has several clearly defined interventions. Therefore, MTMS will be the term used to describe the activity of MTM in various patient populations.

With the passage of the Patient Protection and Affordable Care Act and the Health Care and Education Reconciliation Act of 2010, pharmacists have tremendous opportunities in the implementation of health care reform.[6,7] One of the hallmarks of this law is delivery system reform. As health care delivery systems change, pharmacists have an opportunity to improve overall quality of care, to become involved in coordinated health care approaches such as medical home teams and accountable care organizations, and to collaborate to improve care for high-risk patients and those with chronic conditions in primary care settings. Chronic diseases are prevalent and costly in the United States. Approximately 133 million (or 45%) of all Americans suffer from at least one chronic condition, and the number is increasing. According to the Centers for Disease Control and Prevention (CDC), in the United States, chronic diseases account for 75% of health care spending, or $5300 per person annually.[8] These chronic conditions are often not singular in nature, with one in four adults having two or more chronic conditions, making treatment efforts even more challenging, and with that number expected to continue to rise over the next several years through the end of 2029.[9]

Pharmacists have additional opportunities because hospitals have financial incentives to improve quality, reduce costs, and decrease hospital-acquired conditions.[6,7] Both patient self-care and medication reconciliation are critical aspects of any MTMS encounter regardless of the setting (ie, inpatient, community, ambulatory, or institutional). Patient self-care requires the patient to take responsibility for the illness; however, the help of a professional to structure healthy self-care is important. For example, patients with diabetes who monitor their blood glucose levels regularly and adjust their diet according to

the guidelines published by the American Diabetes Association (ADA) would be practicing self-care. Self-care is often the work that the patient performs between visits with the provider. The patient should be involved in their own care to ensure the best outcomes.

Medication reconciliation is the comprehensive evaluation of a patient's medication regimen any time there is a change in therapy in an effort to avoid medication errors such as omissions, duplications, dosing errors, or drug interactions, as well as to observe compliance and adherence patterns. This process should include a comparison of the existing and previous medication regimens and should occur at every transition of care in which new medications are ordered, existing orders are rewritten or adjusted, or when the patient has added nonprescription medications to their self-care.[10] Although not a new concept to the profession of pharmacy, there has been heightened awareness and intensified effort in this area of practice as a result of the Joint Commission. In 2005, the Joint Commission announced its National Patient Safety Goal (NPSG) 8A and 8B to *accurately and completely reconcile medications across the continuum of care*. This goal requires institutions to develop and test processes for medication reconciliation in ambulatory and acute care settings.[11] In 2015, the Joint Commission's NPSG 3 continued its focus on improving the safe use of medications, in particular by *maintaining and communicating accurate patient medical information.*[12] In 2020, the Joint Commission's NPSG 3 refined its focus even further, emphasizing recording and passing along correct information about a patient's medications, comparing past and present medication lists, providing written information about the patient's medications, and bringing up-to-date medication lists to all physician appointments.[13]

The Centers for Medicare & Medicaid Services (CMS), the largest purchaser of health insurance in the United States, is directly connecting reimbursement for Medicare services to patient outcomes. CMS developed star ratings as a means to move away from the pay-for-service model of health care and move toward a new quality-based model. CMS annually rates Medicare health plans on a scale of 1 to 5 stars, with 5 stars representing the highest

quality. The star ratings include measures across five broad categories: outcomes, intermediate outcomes, patient experience, access, and process.[14] For specific details and updates, visit https://www.cms.gov/Medicare/Prescription-Drug-Coverage/PrescriptionDrugCovGenIn/Downloads/2020-Star-Ratings-Fact-Sheet-.pdf.

It is important for pharmacists to realize that MTMS are integral to improving health outcomes and are continuing to gain acceptance from payers, in both the private and public sectors. The opportunity for pharmacists to continue to expand their role, while offering high-level care, along with the potential for improvement in pharmacy compensation is in line with the CMS star ratings.

The general approach to an MTMS patient encounter in various clinical settings is discussed in the next sections. **Figure 1-1** provides a visual representation of a systematic process for a comprehensive and effective approach for delivering MTMS.

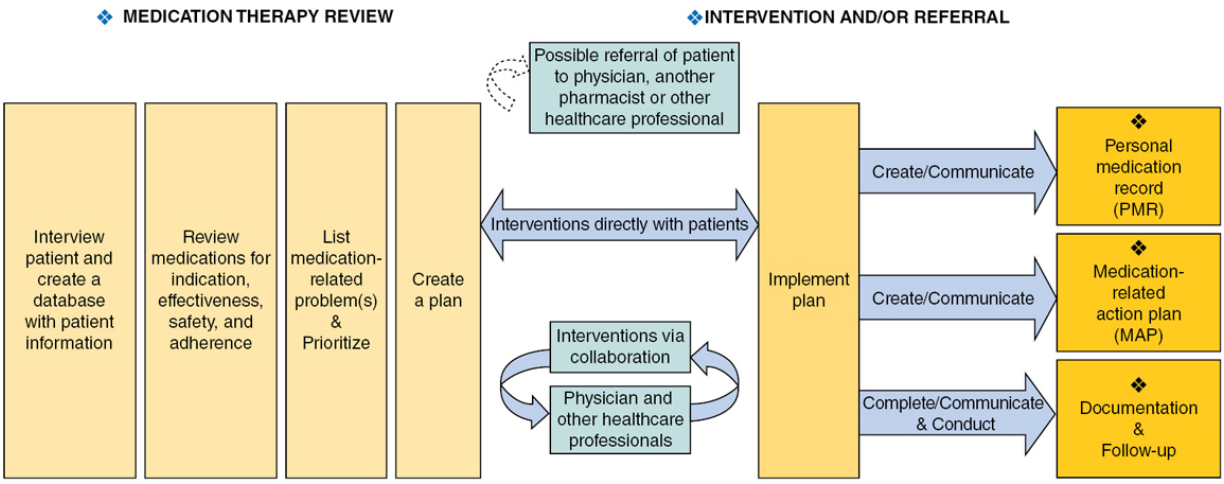

Figure 1-1 General approach to a medication therapy management services (MTMS) patient encounter. Medication therapy management in pharmacy practice: core elements of an MTM service model (version 2.0). *J Am Pharm Assoc (2003)*. 2008;48(3):341–353. © 2008 American Pharmacists Association, with permission.)

SOURCES OF PATIENT INFORMATION

Successful patient assessment and monitoring requires gathering and organizing relevant information.[4,15] The patient, family member, or caregiver is always the primary source of information. The provider asks the patient a series of questions to obtain subjective information that is helpful in making a diagnosis or evaluating ongoing therapy. Likewise, providers without direct access to patient data must also obtain subjective data or measure objective physical data to guide recommendations for therapy and to monitor previously prescribed therapy.

Data-Rich and Data-Poor Environments

In a "data-rich environment," such as a hospital, long-term facility, or outpatient medical clinic, a wealth of information is available to practitioners from the medical record, pharmacy profile, and medication administration record (MAR). In these settings, physicians, nurses, other health care providers, and patients are readily available. This facilitates timely, effective communication among providers involved in the drug therapy decision-making process. Objective data (eg, diagnosis, physical examination, laboratory and other test results, vital signs, weight, medications, medication allergies, intravenous flow rates, and fluid balance) are readily available. The patient record provides information that is needed to identify and assess medical problems, which is necessary to design patient-specific care plans and document MTMS. In some settings, patient insurance information is important to help understand the formulary choices and access to medications.

In a "data-poor environment," such as a community pharmacy, clinicians are often required to make assessments with limited information. Although the information may be limited to (a) the medication profile, (b) patient demographic data, (c) medication allergy history, and (d) the patient's insurance coverage, it is still valuable.

The information in **Table 1-1** is an illustrative summary of sources of patient information.

Table 1-1
Sources of Patient Information

Data-Rich Environment	Data-Poor Environment

Paper Charts
▪ Decreasing use across the practice continuum
▪ Limitations
  ▪ Not consistent from site to site
  ▪ Difficult to access if more than one user
  ▪ Delays in data entry
Electronic Health Record (EHR)
▪ Electronic version of a paper chart
▪ Differs across practice settings
▪ One of the most complete sources of reliable information
▪ Can interface with other software systems in the pharmacy, laboratories, etc
▪ Data shared between systems in real time
	Pharmacy Information Systems (PIS)—Outpatient and Inpatient
	▪ Mainly focus on pharmacy billing, inventory management, production of medication labels
	▪ Limited documentation of clinical pharmacy

Pharmacy information systems (PIS) are generally considered data poor. Early PIS were established for pharmacy billing and inventory management. These initial systems provided medication fill lists, generated patient profiles, and produced medication labels that were valuable to institutional pharmacies as the profession moved toward a unit-dose medication distribution system. More modern functionalities allow for some limited documentation of clinical pharmacy activities, but the PIS are still considered to be data poor.

An initiative by the U.S. Department of Health and Human Services, called the *EHR Incentive Program*, exemplifies the importance of the integration of PIS with other computerized systems.[16] This initiative, the "Meaningful Use of an EHR," allows

Medicare and Medicaid to provide incentive payments to providers and hospitals for the “meaningful use” of certified health information technology products. Eligibility for these incentive payments involves transitioning PIS to a more data-rich clinical information system (CIS), which includes direct computerized physician order entry, clinical decision support, an electronic health record (EHR), an electronic medication administration record (eMAR), and integration of various information systems such as pharmacy and laboratory services. Additional functionality incorporates the use of barcode technology, which allows the ability to track and promote quality assurance during the medication administration process. Information generated by the CIS is electronically transmitted to the pharmacy in real time, eliminating lost, illegible, or incomplete medication orders.

In a data-poor environment, the clinician must be a proactive interviewer and may become an investigator. The investigative approach is direct and requires strong problem-solving abilities and active listening skills. Questions should be formulated to obtain information such as the medication history, actual medication use, patient perception of care, use of over-the-counter (OTC) and natural or herbal products, and health beliefs (cultural or otherwise). This approach can help verify and ensure the accuracy of other data sources. Clinicians should be mindful that not all patients are reliable historians, and some are poor sources of information. Even when the patient is a poor historian, the interview provides critical information (eg, indicator of poor adherence and need for a caregiver or interpreter) that cannot be obtained from other sources.

EFFECTIVE COMMUNICATION AND THE PATIENT INTERVIEW

The ability to use effective communication principles and history-taking skills is crucial to a successful patient interaction.[4,15] The importance of interviewing the patient, how to set the stage for the

interview, general interview rules, and the essential information to be obtained from the interview are outlined in **Table 1-2**. Information obtained from the patient is critical for assessment and planning in MTM.

Table 1-2
Interviewing the Patient

Importance of Interviewing the Patient
Establishes professional relationship with the patient to do the following: ▪ Obtain subjective data on medical problems. ▪ Obtain patient-specific information on drug efficacy and toxicity. ▪ Assess the patient's knowledge about, attitudes toward, and pattern of medication use. ▪ Formulate a problem list. ▪ Formulate plans for medication teaching and pharmaceutical care.
How to Set the Stage for the Interview ▪ Have the patient complete a written health and medication questionnaire, if available. ▪ Make the setting as private as possible. ▪ Maintain eye contact. ▪ Encourage the patient to be descriptive. ▪ Clarify by restatement or patient demonstration (eg, of a technique).
General Interview Rules ▪ Read the chart or patient profile first. ▪ Ask for the patient's permission to conduct an interview or make an appointment to do so. ▪ Begin with open-ended questions. ▪ Move to close-ended questions. ▪ Document interaction.
Information to Be Obtained ▪ History of allergies ▪ History of adverse drug reactions ▪ Weight and height ▪ Drugs: dose, route, frequency, and reason for use ▪ Perceived efficacy of each drug ▪ Perceived side effects

- Adherence to prescribed drug regimen
- Nonprescription medication use (including complementary and alternative medications)
- Possibility of pregnancy in females of childbearing age
- Family or other support systems

Motivational interviewing (MI) is another useful method created by Miller and Rollnick that can be utilized during patient counseling to improve patient adherence to therapy. It is an empathetic and collaborative style of counseling based on five key principles: expressing empathy, developing discrepancy, adapting to resistance, avoiding arguments, and supporting self-efficacy, as seen in **Table 1-3**. The basis of MI is aimed at improving a patient's ambivalence to drug therapy through behavioral changes. It should be noted that MI does not require a long-standing pharmacist–patient relationship to be effective, because individual sessions have been shown to be helpful.[17,18]

Table 1-3
Principles of Motivational Interviewing

Expressing empathy	Convey to your patient that you understand their condition. This will allow the patient to be more open minded.
Develop discrepancy	Point out to the patient that there is a difference between current behavior and being able to reach their goals.
Adapt to resistance	Use different approaches to encourage the patient to channel their resistance into positive change.
Avoid arguments	Do not argue with your patient or force them to view things as you do.
Support self-efficacy	Assist the patient with believing that their own decisions will make a difference to behavioral change. Instead of telling the patient what to do, empower them to figure out what will be effective.

Mental Health Services Administration (US); 1999:chap 3. Treatment Improvement Protocol (TIP) Series, No. 35. http://www.ncbi.nlm.nih.gov/books/NBK64964/.

OBTAINING A PATIENT HISTORY

Those who provide MTMS should develop standardized forms to record patient information obtained from the patient interview. Standardization facilitates quick retrieval of information, minimizes the inadvertent omission of data, and enhances the ability of other practitioners to use shared records.[4,15]

The patient interview and record can be divided into sections with subjective and objective data as well as an assessment and plan (including expected outcomes). Components of subjective and objective data are the medical history, medication history, and social history. In some situations, histories can be supplemented by the generation of flowchart diagrams to monitor changes in specific variables with time. These charts and documentation systems may be incorporated into the EHR, PIS, or a similar electronic platform.

Medical History

A medical history is essential to the provision of MTMS. It can be as extensive as the medical records that are maintained in an institution or a physician's office, or it can be a simple patient profile that is maintained in a community pharmacy. The purpose of the medical history is to identify significant past medical conditions or procedures; identify, characterize, and assess current acute and chronic medical conditions and symptoms; and gather all relevant health information that could influence drug selection or dosing (eg, function of major organs such as the gastrointestinal tract, liver, and kidney; height and weight, including recent changes in either; age and sex; pregnancy and lactation status; and special nutritional needs). Not all interviews require the interviewer to ask for this much general information; however, in a data-poor environment, more

information is required directly from the patient. A more focused interview may be appropriate in settings in which the information required is available electronically or is specific to a single disease state.

CASE 1-1

QUESTION 1: P.J., a 45-year-old female of normal height and weight, states that she has diabetes.

What questions might the practitioner ask P.J. to determine whether type 1 or type 2 diabetes should be documented in her medical history?

Patients usually can enumerate their medical problems in a general way, but the practitioner often will have to probe more specifically to refine the diagnosis and assess the severity of the condition. Diabetes mellitus is used to illustrate the types of questions that can be used to gather important health information and assess drug therapy. The following questions should generate information that will help determine whether P.J. has type 1 or type 2 diabetes.

- How old were you when you were told you had diabetes?
- Do any of your relatives have diabetes? What do you know of their diabetes?
- Do you remember your symptoms? Please describe them to me.
- What medications have you used to treat your diabetes?

When questions such as these are combined with knowledge of the pathophysiology of diabetes, appreciation of the typical presenting signs and symptoms of the disease, and understanding of the drugs generally used to treat both forms of diabetes, meaningful MTM can be provided.

Medication History

In the community pharmacy setting, patients generally present themselves in one of four ways: (a) with a self-diagnosed condition

for which nonprescription drug therapy is sought, (b) with a newly diagnosed condition for which a drug has been prescribed, (c) with a chronic condition that requires a refill of a previously prescribed drug or the initiation of a new drug, or (d) upon referral from their health plan or provider, or self-referral for focused medication therapy review (MTR).

In the first and second situations, the practitioner must confirm the diagnosis using disease-specific questions, as illustrated in Case 1-1, Question 1. In the third situation, the practitioner uses the same type of questioning as in the first two situations; however, this time the practitioner needs to evaluate whether the desired therapeutic outcomes have been achieved. The practitioner must evaluate the information gleaned during follow-up visits in the context of the history and incorporate it into their assessment and medication action plan (MAP). In the fourth situation, in which patients require a focused MTR, the medication and medical history information are equally important. Without the medical history, it is not possible to evaluate whether the drug therapy is appropriate, and without an accurate medication history, it is not possible to determine whether the patient has reached the desired goals of therapy for her condition.

The goal of the medication history is to obtain and assess the following information: the specific prescription and nonprescription drugs that the patient is taking (such as OTC medications, botanicals, dietary supplements, recreational drugs, alcohol, tobacco, and home remedies); the intended purpose or indications for each of these medications; how it is taken (eg, route, ingestion in relation to meals), how much, and how often these medications are used; how long these agents have been taken or used (start and stop dates); whether the patient believes that any of these agents are providing therapeutic benefit; whether the patient is experiencing or has experienced any adverse effects that could be caused by each of these agents (idiosyncratic reactions, toxic effects, adverse effects); whether the patient has stopped taking any of the medications for any reason; and allergic reactions or history of hypersensitivity or other severe reactions to drugs. This information

should be as specific as possible, including a description of the reaction, the treatment, and the date of its occurrence.

A successful medication reconciliation process consists of a standardized systematic approach, with the initial step in this process involving the collection of the best medication history possible from every patient that enters any point in the health care system. Although pharmacists are uniquely qualified and have demonstrated increased accuracy in acquiring the medication history,[19] medication reconciliation requires a multidisciplinary effort in which all available resources are integrated into each step of the process when appropriate.[20] Shared accountability using key members of the health care team such as nurses, pharmacy technicians, pharmacists, and prescribers is essential in this process. Once an accurate medication history is obtained, this information is used to ensure that as the patient moves through the health care system, any deviation from the prescribed regimen is deliberate and based on acute changes in the patient's condition. If an observed discrepancy is the result of an intended therapeutic decision by the prescribing clinician, appropriate documentation with either the reason for or intention to change, hold, or discontinue the medication should be completed in a manner that is clear to all members of the health care team. Unintentional variances in the medication lists should be considered as potential medication errors pending clarification from the prescribing clinician.

Medication errors most commonly occur during transitions of care. It is essential to conduct medication reconciliation when a patient is admitted to or discharged from a health care facility.[21,22] A crucial final step in the reconciliation process, and a vital piece of MTMS, occurs at discharge to avoid therapeutic duplication, drug interactions, and omissions of medications that may have been discontinued or placed on hold during hospitalization. On departure from a health care facility, a complete list of the patient's medications must be communicated to the patient and the next provider of service regardless of the setting. This process allows for informed prescribing decisions and creates a safer environment for patients by

improving the accuracy of medication administration throughout the continuum of care.

Perhaps the most important aspect of the medication history is to ensure that no assumptions related to medication use go unverified with the patient. The provider should ask questions related to how the current medication therapy is actually taken by the patient. The interviewer should then compare the use of medications as defined by the patient to the prescription information on the prescription bottle or in the PIS/EHR. This information may identify discrepancies or misunderstandings between the prescriber and the patient. The patient may not have adequate health literacy, and the interpretation of the medication instructions printed on the bottle or described by a health professional may not be understandable to a patient. The review of the medication history is an ideal time to identify and clarify such misunderstandings.

CASE 1-1, QUESTION 2: P.J. has indicated that she is injecting insulin to treat her diabetes. What questions might be asked to evaluate P.J.'s use of and response to insulin?

The following types of questions, when asked of P.J., should provide the practitioner with information on P.J.'s understanding about the use of and response to insulin.

DRUG IDENTIFICATION AND USE

- What type of insulin do you use?
- How many units of insulin do you use?
- When do you inject your insulin?
- Where do you inject your insulin?
- Please show me how you usually prepare your insulin for injection. (This allows the patient to demonstrate a skill.)
- What, if anything, keeps you from taking your insulin as prescribed?

ASSESSMENT OF THERAPEUTIC RESPONSE

- How do you know your insulin is working?
- What blood glucose levels are you aiming for?
- What foods or meals do you find affect your blood sugar most?
- How often and when do you test your blood glucose level?
- Do you have any blood glucose readings that you could share with me?
- Please show me how you test your blood glucose.
- What is your understanding of the hemoglobin A_{1c} blood test?
- When was the last time you had this test done?
- What were the results of the last hemoglobin A_{1c} test?

ASSESSMENT OF ADVERSE EFFECTS

- Do you ever experience reactions from low blood glucose?
- What symptoms warn you of such a reaction?
- When do these typically occur during the day?
- How often do they occur?
- What circumstances seem to make them occur more frequently?
- What do you do when you have low blood glucose?

The patient's responses to these questions on drug use, therapeutic response, and adverse effects will allow a quick assessment of the patient's knowledge of insulin and whether she is using it in a way that is likely to result in blood glucose concentrations that are neither too high nor too low. The responses to these questions should also provide the practitioner with insight about the extent to which the patient has been involved in establishing and monitoring therapeutic outcomes. Based on this information, the practitioner can begin to formulate the patient's therapeutic plan.

Social History

The social history is used to determine the patient's occupation and lifestyle; important family relationships or other support systems; any particular circumstances (eg, a disability) or stresses in her life that could influence the MAP; and attitudes, values, and feelings about health, illness, and treatments.

CASE 1-1, QUESTION 3: A patient's occupation, lifestyle, insurance status, ability to pay, and attitudes often can determine the success or failure of drug therapy. Therefore, P.J.'s prescription drug coverage, nutritional history, her level of activity or exercise in a typical day or week, the family dynamics, and any particular stresses that may affect glucose control need to be documented and assessed. What questions might be asked of P.J. to gain this information?

WORK

- Describe your typical workday and a typical weekend day.

INSURANCE/COST

- What type of prescription drug coverage do you have? How much do you pay for your insulin and diabetic supplies? How often do you go without your insulin or supplies because of cost?

EXERCISE

- Describe your exercise habits. How often, how long, and when during the day do you exercise? Describe how you change your meals or insulin when you exercise.

DIET

- How many times per day do you usually eat? Describe your usual mealtimes.
- What do you usually eat for each of your main meals and snacks?
- Are you able to eat at the same time each day?
- What do you do if a meal is delayed or missed?
- Who cooks the meals at home? Does this person understand foods to prepare for someone with diabetes?

- How often do you eat meals in a restaurant?
- How do you order meals in a restaurant to maintain a proper diet for your diabetes? (*Note:* This is asked of patients who frequently dine in restaurants.)

SUPPORT SYSTEMS

- Who else lives with you? What do they know about diabetes? How do they respond to the fact that you have diabetes? How do they help you with your diabetes management? Does it ever strain your relationship? What are the issues that seem to be most troublesome? (*Note:* These questions apply equally to the workplace or school setting. Often, the biggest barrier to multiple daily injections is refusal of the patient to inject insulin while at work or school.)

ATTITUDE

- How do you feel about having diabetes?
- What worries or bothers you most about having diabetes? (*Note:* Participate in the patient's care. This approach is likely to enhance the patient–provider relationship, which should translate into improved care.)

APPROACH TO AND ASSESSMENT OF PATIENT THERAPY

The provider–patient encounter will vary based on the location and type of services provided and access to necessary information. However, the general approach to the patient encounter should follow the problem-oriented medical record (POMR). Organizing information according to medical problems (eg, diseases) helps break down a complex situation (eg, a patient with multiple medical problems requiring multiple drugs) into its individual parts.[1,3] The medical community has long used a *POMR* or *SOAP note* to record

information in the medical record or chart using a standardized format (**Table 1-4**). Each medical problem is identified, listed sequentially, and assigned a number. *Subjective* and *objective* data in support of each problem are delineated, an *assessment* is made, and a *plan* of action identified. The first letter of the four key words (*s*ubjective, *o*bjective, *a*ssessment, and *p*lan) serves as the basis for the SOAP acronym.

Table 1-4

Elements of the Problem-Oriented Medical Record

Problem name: Each "problem" is listed separately and given an identifying number. Problems may be a patient report of a symptom (eg, headache), a laboratory abnormality (eg, hypokalemia), or a specific disease name if prior diagnosis is known. When monitoring previously described drug therapy, more than one drug-related problem may be considered (eg, lack of adherence, an adverse drug reaction or drug interaction, or inappropriate dose). Under each problem name, the following information is identified:	
Subjective	Information that explains the reason for the encounter. Information that the patient reports concerning symptoms, previous treatments, medications used, and adverse effects encountered. These are considered nonreproducible data because the information is based on the patient's interpretation and recall of past events.
Objective	Information from physical examination, laboratory test results, diagnostic tests, pill counts, and pharmacy patient profile information. Objective data are measurable and reproducible.
Assessment	A brief but complete description of the problem, including a conclusion or diagnosis that is supported logically by the abovementioned subjective and objective data. The assessment should not include a problem or diagnosis that is not defined earlier.
Plan	A detailed description of recommended or intended further workup (laboratory tests, radiology, consultation), treatment (eg, continued observation, physiotherapy, diet, medications, surgery), patient education (self-care, goals of therapy, medication use, and monitoring), monitoring, and follow-up relative to the abovementioned assessment.

Sometimes referred to as the *SOAP* (*s*ubjective, *o*bjective, *a*ssessment, *p*lan) note.

The POMR is a general approach and helps focus on the encounter, which provides a structure for the documentation of the services provided. The following section describes the POMR and SOAP note in more detail.

Problem List

Problems are listed in order of importance and are supported by the subjective and objective evidence gathered during the patient encounter. Each problem in the list can then be given an identifying number. All subsequent references to a specific problem can be identified or referenced by that number (eg, “problem 1” or simply “1”). These are generally thought of in terms of a diagnosed disease, but they also may be a symptom complex that is being evaluated, a preventive measure (eg, immunization, contraception), or a cognitive problem (eg, lack of adherence). Any condition that requires a unique management plan should be identified as a problem to serve as a reminder to the practitioner that treatment is needed for that problem. Different settings and activities or clinical services will determine the priority of the problems identified.

Medical problems can be *drug related*, including prescribing errors, dosing errors, adverse drug effects, adherence issues, and the need for medication counseling. Drug-related problems may be definite (ie, there is no question that the problem exists) or possible (ie, further investigation is required to determine whether the problem really exists). The most commonly encountered types of drug-related problems are listed in **Table 1-5**.[4,15]

Table 1-5
Drug-Related Problems

Drug Needed
Drug indicated but not prescribed; a medical problem has been diagnosed, but there is no indication that treatment has been initiated (maybe it is not needed).
Correct drug prescribed but not taken (lack of adherence)
Wrong or Inappropriate Drug

ALGrawany

No apparent medical problem justifying the use of the drug
Drug not indicated for the medical problem for which it has been prescribed
Medical problem no longer exists.
Duplication of other therapy
Less expensive alternative available
Drug not covered by formulary
Failure to account for pregnancy status, age of patient, or other contraindications
Incorrect nonprescription medication self-prescribed by the patient
Recreational drug use
Wrong Dose
Prescribed dose too high (includes adjustments for renal and hepatic function, age, body size)
Correct prescribed dose but overuse by patient (overadherence)
Prescribed dose too low (includes adjustments for age, body size)
Correct prescribed dose but underuse by patient (underadherence)
Incorrect, inconvenient, or less-than-optimal dosing interval (consider use of sustained-release dosage forms)
Adverse Drug Reaction
Hypersensitivity reaction
Idiosyncratic reaction
Drug-induced disease
Drug-induced laboratory change
Drug Interaction
Drug–drug interaction
Drug–food interaction
Drug–laboratory test interaction
Drug–disease interaction

The distinction between medical problems and drug-related problems sometimes is unclear, and overlap can exist. For example, a medical problem (ie, a disease, syndrome, symptom, or health condition) can be prevented, cured, alleviated, or exacerbated by

medications. When assessing drug therapy, several situations could exist: treatment is appropriate and therapeutic outcomes have been achieved; drugs that have been selected are ineffective or therapeutic outcomes are partially achieved; dosages are subtherapeutic or medication is taken improperly; an inappropriate drug for the medical condition being treated has been prescribed or is being used; or the condition is not being treated.

Likewise, a drug-related problem can cause or aggravate a medical problem. Such drug-related problems could include hypersensitivity reactions; idiosyncratic reactions; toxic reactions secondary to excessive doses; adverse reactions (eg, insulin-induced hypoglycemia or weight gain); drug–drug, drug–disease, drug–laboratory test, and drug–lifestyle interactions; or polypharmacy, which may increase the risk of adverse drug events.[23]

Subjective and Objective Data

Subjective and objective data in support of a problem are important because assessment of patients and therapies requires the gathering of specific information to verify that a problem continues to exist or that therapeutic objectives are being achieved. Subjective data refer to information provided by the patient or another person that cannot be confirmed independently. This is the data most commonly obtained during a patient interview. Objective data refer to information observed or measured by the practitioner (eg, laboratory tests or blood pressure [BP] measurements). Objective data are most commonly obtained from the electronic medical record (EMR) or paper chart (data-rich environment). However, some objective data can be obtained in data-poor environments. In the absence of a medical record, weight, height, pulse, BP, blood glucose readings, and other objective information can be gathered during the provider–patient encounter.

CASE 1-2

QUESTION 1: P.N., a 28-year-old male, has a BP of 140/100 mm Hg.

What is the primary problem? What subjective and objective data support the problem, and what additional subjective and objective data are not provided, but usually are needed, to define this particular problem?

The primary problem is hypertension. No subjective data are given. The objective data are the patient's age, sex, and BP of 140/100 mm Hg. Each of these is important in designing a patient-specific therapy plan. Because hypertension often is an asymptomatic disease (see Chapter 9, Essential Hypertension), subjective reports such as headache, tiredness or anxiety, shortness of breath (SOB), chest pain, and visual changes usually are absent. If long-term complications such as rupturing of blood vessels in the eye, glomerular damage, or encephalopathy were present, subjective symptoms might be blurring or loss of vision, fatigue, or confusion. Objective data would include a report by the physician on the findings of the chest examination (abnormal heart or lung sounds if secondary heart failure [HF] has developed), an ocular examination (eg, presence of retinal hemorrhages), and laboratory data on renal function (blood urea nitrogen, creatinine, or creatinine clearance). To place these complications in better perspective, the rate of change should be stated. For example, the serum creatinine has increased from a level of 1 mg/dL 6 months ago to a value of 3 mg/dL today. Vague descriptions such as "eye changes" or "kidney damage" are of little value because progressive damage to these end organs results from uncontrolled high BP and disease progression needs to be monitored more precisely.

CASE 1-3

QUESTION 1: C.S., a 58-year-old female, reports fatigue, ankle swelling, and SOB, especially when lying down, for the past week. Physical examination shows distended neck veins, bilateral rales, an S_3 gallop rhythm, and lower extremity edema. A chest radiograph shows an enlarged heart. She is diagnosed with HF and is being treated with furosemide and digoxin.

What is/are the primary problem(s)? What subjective and objective data support the problem(s)? What additional subjective and objective data are not provided but usually are needed to define this (these) particular problem(s)?

The primary problem is systolic HF. Subjectively, C.S. claims to be experiencing fatigue, ankle swelling, and SOB, especially when lying down. She claims to have been taking furosemide and digoxin. An expanded description of these symptoms and her medication use would be helpful. The findings on physical examination and the enlarged heart on chest radiograph are objective data in support of the primary problem of HF. In addition, other objective findings that would help in her assessment would be the pulse rate, BP, serum creatinine, serum potassium concentration, digoxin blood level, a more thorough description of the rales on lung examination, extent of neck vein distension, and degree of leg edema. Pharmacy records could be screened to determine current dosages and refill patterns of the medications.

In this case, a second primary problem may be present. Current recommendations for the management of HF include use of an angiotensin-converting enzyme (ACE) inhibitor before or concurrent with digoxin therapy. Thus, a possible drug-related problem is the inappropriate choice of drug therapy (“wrong drug”). The patient or prescriber should be consulted to ascertain whether an ACE inhibitor has been used previously, any contraindications exist, or possible adverse effects were encountered.

Assessment

After the subjective and objective data have been gathered in support of specific listed problems, the practitioner should assess the acuity, severity, and importance of these problems. They should then identify all factors that could be causing or contributing to the problem. The assessment of the severity and acuity is important because the patient expects relief from the symptoms that are of particular concern at this time. During the initial encounter with a patient, it might be discovered that the medical problem is only a symptom complex and that a diagnosis is needed to more accurately identify the problem and further define its severity.

The assessment is usually performed during or immediately after the data gathering, while the provider keeps in mind evidence-based practices. For example, if diabetes is assessed and pertinent subjective data (medication history, social history, diet, exercise, etc) and objective data exist (laboratory test results such as hemoglobin A_{1c}, low-density lipoprotein cholesterol [LDL-C], BP, etc), then the assessment of diabetes may be to determine whether the patient is meeting the goals for the disease as defined by the ADA. If the patient is not at goal, then the explanation of the reasons why would be described in the assessment, and the plan would then be centered on helping that patient get to goal. Sometimes, the distinction between subjective information provided by the patient and assessments made by the practitioner are confused in the POMR. What the patient reveals belongs in the subjective data, and how the provider interprets it belongs in the assessment. For example, a patient stating that she is having difficulty affording her medications belongs in the subjective information. However, a patient appearing to have cost-related lack of adherence belongs in the assessment, because it is the provider's interpretation of what the patient has stated.

DRUG THERAPY ASSESSMENT

A responsibility of the practitioner is to monitor the response of patients to prescribed therapeutic regimens. The purpose of drug therapy monitoring is to identify and solve drug-related problems and to ensure that all therapeutic objectives are being achieved. Unless proved otherwise, the medical diagnosis should be assumed to be correct. On occasion, the diagnosis may not be readily apparent, or a drug-induced problem may have been diagnosed incorrectly as being a disease entity.

Health care practitioners share the responsibility of assessing and monitoring patient drug therapy. For the pharmacist, medication reconciliation and the drug therapy assessment may occur in many practice settings, including the community pharmacy while dispensing or refilling prescriptions or counseling patients, during an

MTMS encounter in the home or in the clinic, while assessing therapy for the hospitalized patient, or as part of routine monthly evaluations of patients residing in long-term care facilities. Many states have enacted legislation allowing pharmacists to develop collaborative drug therapy agreements with physicians for disease-state management of common disorders such as asthma, diabetes, dyslipidemia, and hypertension. Additional services commonly provided by pharmacists through collaborative drug therapy agreements include anticoagulation monitoring, emergency contraception, and immunizations.[6] These services often involve more detailed drug therapy evaluation and assessment and may occur within or outside the traditional pharmacy setting. Regardless, the patient's need, time constraints, working environment, and practitioner's skill level govern the extent of monitoring. Similarly, the exact steps used to monitor therapy and the order in which they are executed need to be adapted to a practitioner's personal style. Thus, the examples given in this chapter should be used by the reader as a guide rather than as a recipe in a cookbook.

Plan

The next step in the problem-oriented (ie, SOAP) approach is to create a plan, which at the minimum should consist of a diagnostic plan and a MAP that includes patient education. The plan is the action that was justified in the assessment. The plan is clear and direct and does not require explanation (this should be explained in the assessment). For example, if a patient is experiencing constipation while taking an opioid pain reliever, the plan would be to recommend a stool softener or stimulant laxative such as docusate sodium. The plan should also include any follow-up that would be necessary as a result of the action taken.

Patient Education

Educating patients to better understand their medical problem(s) and treatment is an implied goal of all treatment plans. This process is categorized as the development of a patient education plan. The level of teaching has to be tailored to the patient's needs, health literacy, willingness to learn, and general state of health and mind. The patient should be taught the knowledge and skills needed to achieve and evaluate their therapeutic outcome. An important component of the patient education plan emphasizes the need for patients to follow prescribed treatment regimens.

The POMR will allow the provider to focus on the interview and the encounter independent of the site or service offered. The POMR facilitates documentation of the provision of MTMS across multiple sites and services (across the continuum of care).

The next few sections discuss how to approach MTMS in various clinical settings.

MEDICATION THERAPY MANAGEMENT SERVICES IN THE COMMUNITY PHARMACY OR AMBULATORY SETTING

The core elements of MTMS have been described by the APhA and the National Association of Chain Drug Stores (NACDS).[20] According to these organizations, the core elements of MTMS should include the following components:

1. Medication therapy review (MTR)
2. Personal medication record (PMR)
3. Medication action plan (MAP)
4. Intervention or referral
5. Documentation and follow-up

Medication Therapy Review

The MTR may be a comprehensive review, including medication reconciliation, in which the provider reviews all of the medications the patient is currently taking, or it may be a focused review of one medication-related issue such as an adverse event. Examples of services provided during the MTR are described in **Table 1-6**. MTR is dependent on the information that is available from the patient or other data sources.

Table 1-6
Examples of Services Provided During a Medication Therapy Review

- Assess the patient's health status.
- Assess cultural issues, health literacy, language barriers, financial status, and insurance coverage or other patient characteristics that may affect the patient's ability to take medications appropriately.
- Interview the patient or caregiver to assess, identify, and resolve actual or potential adverse medication events, therapeutic duplications, untreated conditions or diseases, medication adherence issues, and medication cost considerations.
- Monitor medication therapy, including response to therapy, safety, and effectiveness.
- Monitor, interpret, and assess patient laboratory values, especially because they relate to medication use/misuse.
- Provide education and training on the appropriate use of medications.
- Communicate appropriate information to other health professionals, including the use and selection of medication therapy.

Personalized Medication Record

Regardless of the setting, a necessary tool to help with the gathering of the medication information is the PMR. This medication record should be updated after any change in medication therapy and should be shared with other health care providers. The goal of this record is to promote self-care and ownership of the medication regimen.[24] The PMR should be used at all levels of care, thereby facilitating the medication reconciliation process required across the continuum of care. An example of a PMR is shown in **Figure 1-2**.

My Medication Record

Name: MC ———————— Birth Date: May 28, 1939 ————————

Include all of your medications on this record: prescription medications, nonprescription medications, herbal products, and other dietary supplements. Always carry your medication record with you and show it to all your doctors, pharmacists, and other health care providers.

Drug	Take for…	When do I tak e it?	Start	Stop	Doctor	Special Instructions
Lisinopril	40 mg	High blood pressure	Once daily	1/2/15	Sara Smith, MD	
Metoprolol	50 mg	High blood pressure	Twice daily	1/2/15	Sara Smith, MD	9 A.M. and 9 P.M.
Glipizide	5 mg	Diabetes	Once daily	1/2/15	Sara Smith, MD	9 A.M.
Indomethacin	50 mg	Back Pain	Up to 3 times daily if needed	1/2/15	Sara Smith, MD	Take with food. Do not take this medicine with other anti-inflammatory medicines (e.g., ibuprofen, naproxen). Do not take this medication unless you have pain.
Crestor (rosuvastatin)	40 mg	Cholesterol	Once daily	4/2/15	Ted Hart, MD	

This sample Personal Medication Record (PMR) is provided only for general informational purposes and does not constitute professional health care advice or treatment. The patient (or other user) should not, under any circumstances, solely rely on, or act on the basis of, the PMR or the information therein. If he or she does so, then he or she does so at his or her own risk. While intended to serve as a communication aid between patient (or other user) and health care provider, the PMR is not a substitute for obtaining professional health care advice or treatment. This PMR may not be appropriate for all patients (or other users). The National Association of Chain Drug Stores Foundation and the American Pharmacists Association assume no responsibility for the accuracy, currentness, or completeness of any information provided or recorded herein.

This form is based on forms developed by the American Pharmacists Association and the National Association of Chain Drug Stores Foundation. Reproduced with permission from APhA and the NACDS Foundation.

Figure 1-2 Example of a personal medication record (PMR).

Once the patient interview has occurred and the PMR has been updated, the provider may still require information to make an assessment. In such cases, the provider must do their best with the available information, or they may obtain missing information such as the medical history or objective data from other providers. In some encounters, obtaining the necessary information and medication reconciliation may take the entire visit, necessitating a follow-up encounter.

Medication Action Plan

If adequate information is available to assess the current problem, a MAP should be developed. Because the MAP is patient centered and is prioritized according to the urgency of need, the provider and the patient should develop the plan together. An example of a MAP can be seen in **Figure 1-3**.

My Medication-Related Action Plan	
Patient:	MC
Doctor (Phone):	Sara Smith, MD
Pharmacy/Pharmacist (Phone):	Rite Mart/Mary John, PharmD
Date Prepared:	May 10, 2015
The list below has important Action Steps to help you get the most from your medications. Follow the checklist to help you work with your pharmacist and doctor to manage your medications AND make notes of your actions next to each item on your list.	
Action steps → What I need to do…	**Notes → What I did and when I did it….**
☐ **For your muscle weakness and soreness** Stop Crestor (rosuvastatin) 40mg. We asked Dr. Hart to change to a lower dose or different agent such as simvastatin. Obtain blood test from Dr. Hart's office. Follow-up with Dr. Hart in 2 days.	
☐ **Medicine Cost** We have asked Dr. Hart to stop Crestor (rosuvastatin) as it is too expensive. A generic medicine such as simvastatin will cost you less and was recommended to Dr. Hart as an alternative. Continue to ask your pharmacist and doctor whether the medications you are taking are covered by your Medicare Part D plan and whether there are any alternatives that may be less expensive.	
☐ **For Pain** Take to Dr. Sara Smith about other pain medications, because the indomethacin may not be the best choice for you due to its side effects/ Some choices might include other medications such as Vicodin (hydrocodone and acetaminophen), over-the-counter acetaminophen, or naproxen or ibuprofen.	
My next appointment with my pharmacist is on: _____ (date) at _____ ☐ AM ☐ PM	
This sample Medication-Related Action Plan (MAP) is provided only for general informational purposes and does not constitute professional health care advice or treatment. The patient (or other user) should not, under any circumstances, solely rely on, or act on the basis of, the MAP or the information therein. If he or she does so, then he or she does so at his or her own risk. While intended to serve as a communication aid between patient (or other user) and health care provider, the MAP is not a substitute for obtaining professional health care advice or treatment. This MAP may not be appropriate for all patients (or other users). The National Association of Chain Drug Stores Foundation and the American Pharmacists Association assume no responsibility for the accuracy, currentness, or completeness of any information provided or recorded herein.	

This form is based on forms developed by the American Pharmacists Association and the National Association of Chain Drug Stores Foundation. Reproduced with permission from APhA and the NACDS Foundation.

Figure 1-3 Example of a medication action plan (MAP).

Intervention and Referral

The MAP often describes the intervention performed in an MTM encounter and may serve as documentation that can be shared with the patient and other health care providers (similar to the PMR). The primary purpose of the MAP is to make the action plan patient centered and to provide the patient with documentation of what they need to do next in the action plan. It also provides space for the patient to document what they did related to this action and when it was done. In some instances, the MAP may involve referral to another provider (a physician or pharmacist with additional

qualifications) if the issue is beyond the scope of the intervening pharmacist.

Coordination of care is a key element of MTMS and MTR.[1] This may include improving the communication between the patient and other health care providers, enhancing the patient's understanding of their health issues or concerns, maximizing health insurance coverage, advocating on behalf of the patient to get the needed medications using available resources and programs, and various other functions that will improve the patient's understanding of their health care environment and promote self-care. Coordination of care may be the primary action taken on behalf of the patient and may be included in the MAP.

Documentation and Follow-up

The development of a documentation process is a necessary component of MTMS.[24] Documentation should be standardized and based on the POMR format. All appropriate records, including the PMR and MAP, should be shared with other providers to promote communication and continuity of care. If the encounter requires follow-up, the documentation should reflect the timing of the follow-up care, and any expectations of the patient and providers should be included. Thorough documentation of the encounter allows all providers to quickly assess the progress of the patient and determine that the desired outcome has been achieved.

An important aspect of documenting the encounter is to submit billing for the encounter when appropriate. Those who provide MTMS should understand the reimbursement process to obtain compensation for providing these valuable cognitive services. Sources of reimbursement can be categorized into two, Medicare Part D and non-Medicare D payers (eg, employer-based health plans, state-sponsored MTM programs in some states, Accountable Care Organizations, and directly to patients if they agree to receive MTMS).

The implementation of Medicare Part D in 2006 allowed pharmacists in pharmacies contracted with prescription drug plans to provide MTMS to plan-identified Medicare recipients. Pharmacists bill these plans through the contracted pharmacy using a national provider identifier (NPI) and CPT codes. The NPI number designates the provider to be paid, and the CPT determines the amount of payment based on the services rendered. There have been substantial changes to the Part D MTM program requirements since 2006 regarding eligibility criteria, types of MTMS provided, and reporting requirements, creating more opportunities for pharmacists to provide MTMS to Medicare recipients.[25]

Visit the 2019 Medicare Part D MTM Fact Sheet for the latest details on eligibility criteria and the MTMS that are required: https://www.cms.gov/Medicare/Prescription-Drug-Coverage/PrescriptionDrugCovContra/Downloads/CY2019-MTM-Fact-Sheet.pdf.

The CPT codes specific to pharmacists providing MTMS include the following:

CPT 99605: Initial face-to-face assessment or intervention by a pharmacist with the patient for 1 to 15 minutes

CPT 99606: Subsequent face-to-face assessment or intervention by a pharmacist with the patient for 1 to 15 minutes

CPT 99607: Each additional 15 minutes spent face-to-face by a pharmacist with the patient; used in addition to 99605 or 99606

For more information about the MTM CPT Codes, visit the Pharmacist Services Technical Advisory Coalition (PSTAC) website at www.pstac.org/services/mtms.codes.html.

Pharmacists should know that all Medicare D payers may not use CPT codes and that non-Medicare D payers may have their own billing procedures. It is essential to become familiar with specific billing methods and any pertinent codes. Furthermore, it is important to realize that reimbursement for MTMS varies by plan and negotiated contract. Pharmacists have also developed patient self-pay reimbursement strategies and contracts with self-insured employers and state-run Medicaid programs to provide services.[26,27]

The APhA provides additional options to bill payers outside of Medicare Part D if one cannot determine the means to bill the payer (https://www.pharmacist.com/sites/default/files/files/mtm_billing_tips.pdf).

The Patient Protection and Affordable Care Act of 2010 and the Health Care and Education Reconciliation Act of 2010 describe the need for payment reform that promotes improved quality of care. Other providers also see these laws providing new opportunities for pharmacists to participate in care teams such as the patient-centered medical home and pay-for-performance programs to improve medication-related care coordination, quality scores, and patient outcomes.[28,29] The enhanced payment for improving quality in medication-related areas could be used to fund the pharmacist in this activity.

With increasing recognition of MTMS' value both with Medicare and non-Medicare payers and the growing opportunities for pharmacists to provide these services, pharmacists who will be providing MTMS may want to consider certification. For a comparison of the credentialing programs available for pharmacists, requirements, and benefits, visit the National Board of Medication Therapy Management at https://www.nbmtm.org/mtm-certification-truly-authentic/.

CASE 1-4

QUESTION 1: M.C. is a 76-year-old female who comes for a focused MTR appointment at the community pharmacy with her daughter. She has a Medicare Part D prescription drug plan and is asking for help with her medication costs. She indicates that she has type 2 diabetes, hypertension, back pain, and hyperlipidemia. Her medications include lisinopril 40 mg once daily, metoprolol 50 mg twice daily, glipizide 5 mg once daily, indomethacin 50 mg up to three times daily as needed for pain, and rosuvastatin 40 mg once daily. M.C. tells you that she has trouble paying for her rosuvastatin (tier 3, $60 copayment) and would rather have a different generic that costs less (tier 1, $5 copayment). Further, she reports muscle soreness and weakness during the past 3 weeks.

What is the primary problem? What objective information can be obtained in a community pharmacy setting? What additional information is necessary to

determine the cause of her problem? How would a clinician assess and document her problem(s) in a SOAP format?

Although the patient presented for an MTR, the primary problem is the patient's self-reported muscle weakness and soreness during the past 3 weeks. Assuming that M.C. is a patient of this pharmacy, the practitioner could gather the necessary medication history from the PIS. Because the patient is present, this is a good opportunity to develop a PMR with M.C. This process will help quickly identify any medication discrepancies between the pharmacy computer system and the patient's understanding of medication administration. If discrepancies are noted, the practitioner can clarify them with M.C. right away as part of the intervention. The PMR should also include a section to list medication allergies. The type of reaction should also be included on the PMR so that other providers will know the severity of the medication allergy (ie, intolerance vs anaphylactic reaction). Based on the data gathered from the pharmacy computer and M.C., a PMR (depicted in Fig. 1-3) could be developed.

Reviewing the medications alone often does not provide enough information to determine whether M.C. is experiencing a medication-related event. Further questioning related to the onset of her symptoms of muscle soreness and weakness may help determine whether this is a medication-related problem.

The practitioner can develop an assessment from this questioning and the PMR of the current problem that she is experiencing. As indicated on the PMR, M.C. started rosuvastatin most recently. The initiation of this medication corresponds to the onset of her recent soreness and weakness. β-Hydroxy-b-methylglutaryl-CoA (HMG-CoA) reductase inhibitors such as rosuvastatin are known to cause myositis, or muscle breakdown, which may lead to weakness and muscle soreness. Furthermore, the prescribed dose is high for a female of M.C.'s age. Based on this information, an assessment of the problem can be pursued. If rosuvastatin is the suspected agent, the plan would include actions necessary to solve the problem or to determine whether rosuvastatin is the cause of her muscle soreness and weakness. Unfortunately, not all of the necessary information is

available (eg, her baseline cholesterol, serum creatinine, liver function tests, or creatine kinase levels) to develop a formal plan of action to resolve the adverse medication event. However, part of the plan may be to obtain the laboratory test results necessary to identify or act on the adverse medication event. An example of the documentation of the SOAP note follows:

PRIMARY PROBLEM

Muscle soreness and weakness (possible adverse medication event)

SUBJECTIVE

M.C. reports weakness and soreness, predominantly in her legs during the past 3 weeks. She has difficulty rising from her chair after sitting for long periods and describes the pain as aching. The patient reports taking her medications as prescribed and rarely misses a dose.

OBJECTIVE

Total cholesterol: 137 mg/dL; LDL-C: 56 mg/dL; high-density lipoprotein (HDL): 54 mg/dL; Triglycerides: 136 mg/dL
Temperature: 98.5 °F (36.94 °C)
Blood pressure: 144/68 mm Hg

ASSESSMENT

M.C. has muscle weakness and soreness in her large muscle groups. According to the American College of Cardiology and the American Heart Association, M.C. is considered to be at risk for heart disease because of her age and concurrent disease states.[30] Her current lipid therapy is rosuvastatin 40 mg once daily, which was started by her cardiologist 6 weeks ago. The initiation of rosuvastatin 40 mg correlates to the timing of her muscle soreness and weakness. HMG-CoA reductase inhibitors (ie, rosuvastatin) are known to cause myositis or myalgias, and this patient is at particular risk given her age, sex, and starting dose. It is possible that the rosuvastatin could be causing her muscle soreness and weakness.

Other lipid-lowering agents could be tried or the dose of rosuvastatin could be reduced, which might eliminate or reduce this adverse event. A creatine kinase level should be obtained to determine the severity of myositis. Serum creatinine should also be measured because myositis can lead to renal damage and rhabdomyolysis in severe cases; however, this is usually accompanied by fever and other symptoms that the patient is not currently experiencing.

PLAN

Drug-Related Adverse Event

- Discussed the possibility of an adverse medication event with the patient, which included the signs and symptoms of myalgias and myositis.
- Contacted Dr. Hart (M.C.'s cardiologist) to discuss the current problem with rosuvastatin.
- Per discussion with Dr. Hart, will obtain a creatine kinase level and serum creatinine.
- Discontinue rosuvastatin per the pharmacist's recommendation. Dr. Hart agreed that M.C. should temporarily stop her rosuvastatin until her laboratory values are reviewed.
- Alternative dosing of rosuvastatin 5 mg or another equivalent agent (atorvastatin 10 mg or simvastatin 20 mg) was discussed with Dr. Hart.
- M.C. is to see Dr. Hart in the cardiology clinic in 2 days to discuss the laboratory values and alternative therapies.
- Discussed the entire plan with M.C., and she verbalized understanding of steps that she is to take with respect to her current medication-induced problem.

CASE 1-4, QUESTION 2: From M.C.'s medication profile, what other problems can be identified with her medication therapy? What can be done to address these issues?

There are two remaining issues that may need to be addressed. The first issue relates to the pain medicine (indomethacin) that M.C. is taking. It is suggested that indomethacin may have a higher rate of central nervous system side effects in the elderly compared with other agents in the same class.[31] Furthermore, the American Geriatric Society guidelines on the management of mild-to-moderate persistent pain caution the use of nonsteroidal anti-inflammatory agents in older adults, preferring acetaminophen as a first-line agent.[32] Other prescription medications or nonprescription medication such as acetaminophen alone could be used to help treat M.C.'s pain (see Chapter 55, Pain and Its Management, and Chapter 107, Geriatric Drug Use).

Second, it is not clear from the current information whether the various providers are communicating. It is the responsibility of the pharmacist to help coordinate care among multiple prescribers, as described by the APhA MTMS consensus document.[1] Therefore, it is important to be sure that both providers (Drs. Smith and Hart) receive a copy of the documentation of the issues addressed during the visit (SOAP note).

CASE 1-4, QUESTION 3: What additional information can be provided to M.C. at this time?

Finally, M.C. came into the pharmacy asking for help with her medication costs. To assess this problem, it is important to ask whether there are specific cost issues with a particular drug or whether it is her overall medication regimen that causes her concern. Another question to ask is whether she has stopped taking any medications or changed the way she takes them because of cost. Many patients will discuss cost and adherence issues with their pharmacist because the point of sale for medications occurs at the pharmacy. However, they may not discuss this problem with the prescriber. Cost and lack of adherence because of cost are medication-related problems that the pharmacist must communicate to the prescriber on behalf of the patient. In assessing drug cost,

several steps can be taken. First, determine the patient's ability to pay for medications; implement low-cost, medically appropriate interventions targeted at patient needs; facilitate enrollment into relevant benefit programs; and confirm medication changes with the patient and prescribers.

For M.C., the rosuvastatin is her biggest concern because it costs $60 per month and her Medicare Part D plan lists it as a nonpreferred (tier 3) agent on the formulary. With the possible discontinuation of her rosuvastatin, it is important for the pharmacist to anticipate an alternative lipid-lowering agent and determine a cost-effective alternative that may be appropriate. This information can then be relayed to the prescriber. Furthermore, the alternative lipid-lowering formulary choice can be integrated into the plan developed for the primary issue of muscle soreness and weakness (see Case 1-4, Question 1). The integration of multiple problems is a complicated but an important aspect of the MAP.

As discussed previously, an important part of MTMS involves the MAP. The MAP is a document that may empower the patient and promote self-care. The information on the MAP is important for both the patient and the provider, and it facilitates communication among multiple providers. When a patient presents the PMR and MAP to all providers, complex medication information can be shared across the continuum of care. An example of M.C.'s MAP is included in Figure 1-3.

Because extensive information was communicated to the patient and other providers, follow-up (phone or face-to-face) would be appropriate and necessary to determine the resolution of the medication-related issues identified. Follow-up should occur in a timely manner, likely after M.C. has obtained the necessary laboratory test results and has been evaluated by her cardiologist as outlined in the plan. The follow-up should include questions related to the changes that were (or were not) made based on the practitioner recommendations and any new issues that have surfaced. Follow-up should be considered after any encounter in which an action plan is developed to determine whether the medication-related problem has been resolved. In addition, problems

may be identified and prioritized during the initial visit but, because of time constraints, may not be addressed. A follow-up visit allows for assessment of these problems.

Case 1-4, Question 4: Assuming that the pharmacy provider had an NPI number and a contract with M.C.'s Medicare Part D prescription drug plan, how could the 30 minutes spent with M.C. be billed to her insurance?

Provided that M.C. was identified by her Medicare prescription drug plan as eligible for MTMS, the practitioner could bill for the 30-minute encounter. Using the practitioner's NPI number and the appropriate CPT codes, the practitioner could bill for one CPT 99605 (for the first 15 minutes of initial face-to-face MTM encounter) and one CPT 99607 (for an additional 15 minutes spent with the patient in a face-to-face MTM encounter). M.C.'s Medicare Part D plan may require the practitioner to bill the prescription drug plan initially, and then the plan would pay the community pharmacy directly instead of reimbursing the individual pharmacist. Documentation of the visit would need to be stored at the site of the encounter in case any information was requested from M.C.'s prescription drug plan.

Case 1-4, Question 5: M.C. has just been hospitalized in a large medical center for renal failure and urosepsis. The pharmacist has access to the medical chart, nursing record, MAR, and a computer that directly links to the clinical laboratory. The pharmacists at this facility assess the patient's drug therapy and routinely provide clinical pharmacokinetic monitoring. How would the pharmacist approach M.C. differently in this inpatient setting compared with the pharmacist in Case 1-4, Question 1 who worked in a community pharmacy?

MEDICATION THERAPY MANAGEMENT IN THE ACUTE CARE SETTING

Similar to the outpatient setting, the SOAP format is often used when documenting the encounter of the hospitalized patient; however,

obtaining the information needed poses unique challenges. In this setting, subjective information may be more difficult to obtain at the time of assessment in those patients presenting with cognitive impairment resulting from their acute condition, such as the seriously ill or injured patient. Objective data, on the other hand, are more readily available and retrievable with access to pharmacy, laboratory, and other medical record information. On admission to the health care facility, the medication reconciliation process should be initiated to identify any variances in the admission orders when compared with the patient's home medication list. With acute medical problems superimposed on chronic conditions, it is not unusual to have new medications added and home medications held, changed, or discontinued.

Assessing the appropriateness of drug therapy requires a basic understanding of both pharmacokinetic (eg, absorption, distribution, metabolism, and elimination) and pharmacodynamic (eg, relief of pain with an analgesic or reduction of BP with an antihypertensive agent) principles. This detailed assessment and monitoring is dependent on the availability of robust patient and laboratory data. The inpatient setting is a relatively data-rich environment in which access to needed information is readily available. Knowledge of the patient's height, body weight, and hepatic and renal function are essential for proper dosage considerations. The type of hospitalized patient will vary from the short-stay elective surgery patient to the critically ill hemodynamically compromised patient. The pharmacist must be aware of how pharmacokinetics and pharmacodynamics can be altered throughout the hospitalization or disease-state process in each patient evaluated. This heightened awareness will allow for timely interventions and minimize medication errors resulting from improper or delayed dosage adjustments because the clinical status of the patient changes. Drug level monitoring may be suitable for certain medications and is of great clinical value; nevertheless, it is important to take into consideration clinical response to drug therapy along with the assessment of a specific laboratory value. Accurate interpretation of any drug level requires review of the nursing MAR (or eMAR), evaluating time of drug

administration to serum sample acquisition. When serum drug levels are obtained, they must be reviewed for validity before alterations in medication regimens are made. If a serum drug concentration seems unusually high or low, the clinician must consider all of the various factors that might influence the serum concentration of the drug in that particular patient. When the reason for an unexpected abnormal serum drug concentration is not apparent, the test should be repeated before considering a dose change that may cause supratherapeutic or subtherapeutic concentrations resulting from erroneous data (see Chapter 2, Interpretation of Clinical Laboratory Tests).

When M.C. was seen in the community pharmacy, the pharmacist assessed her chronic conditions, her cost issues, and her drug therapy. Monitoring in the community pharmacy–based MTM program occurs at regular time intervals and is less sensitive to the day-to-day changes of the patient. However, in the inpatient setting, M.C. has acute conditions (renal failure and urosepsis) in addition to her chronic conditions. Monitoring of medication therapy will occur frequently, resulting in a dynamic treatment plan for her acute and chronic conditions.

Although the inpatient setting is relatively data rich, the information gathered and the assessment and plan formulated in the facility must be communicated to other providers once the patient is discharged. At discharge, it is critical to ensure that the patient has follow-up with their primary care physician or coordinated care team in a timely manner. At this point, it is again critical for the pharmacist to perform medication reconciliation to determine exactly what did happen once the patient returned home. This closes the loop at a critical time when the patient is prone to medication errors and readmission.

MEDICATION THERAPY MANAGEMENT AND PHARMACOGENOMICS

The use of genetic information to predict an individual's response to a drug, known as *pharmacogenomics*, is currently factoring into drug design and development. Using genetic information to tailor drug therapy for an individual will reduce the risk of adverse events, potentially improve patient outcomes, and create a more efficient drug development process. By transforming drug therapy into a patient-specific approach, the health care community is one step closer to achieving the new medical paradigm of personalized health care.[33]

MTM can be the vehicle to allow pharmacists to serve an integral role in applying pharmacogenomics into clinical practice to improve the quality and safety of health care. Incorporating pharmacogenomics into MTMS allows pharmacists to lend their expertise to the treatment planning process to optimize treatment outcomes. Pharmacists, working collaboratively with prescribers and laboratory facilities, could review medications prescribed for a patient and the patient's genomic data to then offer an assessment on whether a prospective drug would provide the best fit for the condition and patient. Through MTMS and pharmacogenomics, pharmacists can optimize drug choice and maximize therapy outcomes (see Chapter 4, Pharmacogenomics and Personalized Medicine).

To successfully integrate a pharmacogenomic component within the clinical decision-making process, key pharmacogenomic data must be identified. The challenge is complex, and research has begun to bring the application of pharmacogenomics to patients as part of the health care delivery system. The pharmacy profession must define a process for the application of pharmacogenomic data into pharmacy clinical practice that is aligned with MTMS delivery. A viable business model that encourages and promotes the use of the clinical expertise of pharmacists working in collaboration with other health care providers and laboratories should be developed for these practices. The development of technology solutions that support the pharmacist's role in this emerging field should also be encouraged and directed.[33]

CONCLUSION

MTMS are intended to be applicable to patients in all care settings where the patients or their caregivers can be actively involved with managing their medication therapy. The goals of all pharmacists providing MTMS are to confirm that the patient's medication therapy is ideal and that the best possible outcomes from treatment are achieved. The MTM process needs to be properly documented and accurately shared with all providers who are part of the patient's health care team. As drug therapy and technology options continue to evolve, pharmacists are encouraged to provide and optimize MTMS to improve patient outcomes and medication use.

Interpretation of Clinical Laboratory Tests

Erika Felix-Getzik, Yulia A. Murray, and Stefanie C. Nigro

CORE PRINCIPLES		CHAPTER CASES
1	Laboratory findings should be used to complement other subjective and objective findings and must not be evaluated in isolation. The values must be assessed in context of the clinical situation and incorporate understanding of human physiology.	**Case 2-3 (Question 1)** **Case 2-4 (Question 1), Table 2-2** **Case 2-5 (Questions 1, 2), Table 2-3** **Case 2-6 (Questions 1, 2)**
2	Lack of availability, expense, or inconvenience may limit the usefulness of some clinical laboratory tests. Estimations by means of equations or nomograms may be used in clinical practice to overcome these barriers.	**Case 2-1 (Question 1), Table 2-2**
3	Test reliability is impacted by various	**Case 2-1 (Question 1)** **Case 2-2 (Question 1)**

	factors including statistical and preanalytical variations, accuracy, and precision.	**Case 2-4 (Question 1), Table 2-1, Table 2-2**
4	Laboratory findings can be helpful in assessing clinical disorders, establishing a diagnosis, assessing drug therapy, or evaluating disease progression.	**Case 2-1 (Question 1), Table 2-2** **Case 2-2 (Question 1), Table 2-3** **Case 2-3 (Question 1)** **Case 2-4 (Question 1)** **Case 2-5 (Questions 1, 2)** **Case 2-6 (Questions 1, 2)**

INTRODUCTION

This chapter provides the reader with an overview of laboratory tests commonly used in clinical practice. Specialized laboratory tests, which are used to monitor specific disease states or specific drug therapies, are integrated into the case histories, questions, and answers in the disease-specific chapters of this textbook. Over-the-counter or patient-directed laboratory tests are briefly discussed at the end of this chapter because of their increased availability and use. All stated laboratory ranges were obtained from the key references listed at the end of this chapter.[1–3]

GENERAL PRINCIPLES

Generally, laboratory tests should be ordered only if the results of the test will guide decisions about the care of the patient. Serum, urine, and other bodily fluids can be analyzed routinely; however, the economic cost and impact on the quality of life related to obtaining

these data must always be balanced by benefit to patient-specific outcomes.

Reference Ranges

The term *reference range* is typically preferred in clinical practice rather than *normal range* because there are several factors that contribute to the "normal" value for each individual. Laboratory findings, within and outside the reference range, can be helpful in assessing clinical disorders, establishing a diagnosis, assessing drug therapy, or evaluating disease progression. In addition, baseline laboratory tests are often necessary to evaluate disease progression and response to therapy or to monitor the development of toxicities associated with therapy.

When assessing laboratory findings, it is important to be mindful that values outside the reference range may not require clinical intervention. Values must be assessed in context of the clinical situation and incorporate understanding of human physiology. Likewise, values that fall within the reference range may need further assessment secondary to limitations of the test or impact of biologic or physiologic considerations. Laboratory findings should also be used to complement other subjective and objective findings, and must not be evaluated in isolation.

Laboratory test results are specific to the clinical laboratory conducting the test and can vary based on the type of equipment and testing methods used. Consequently, clinicians should rely on reference ranges listed by their own clinical laboratory when assessing laboratory tests.

Evaluating Laboratory Results

The reference ranges provided in this chapter are for general illustrative purposes. When applying this information to the clinical setting, appropriate clinical assessment and judgment should be applied. Patient-specific attributes such as the individual's age,

biologic sex, race, clinical presentation, medication history, and lifestyle are factors that may influence reported laboratory results and, therefore, must be taken into consideration. Statistical and preanalytical variations are common, and must also be evaluated in the context of the result obtained. Refer to **Table 2-1** for examples of common preanalytical variables.

Table 2-1

Preanalytical Variation: Factors Affecting the Test Result from the Time the Test Is Ordered Until It Arrives at the Laboratory

Variable	Example(s)
Incorrect test ordered	Albumin ordered to assess the impact of recent dietary change (prealbumin better marker for acute changes)
Sample incorrectly labeled	Sample obtained from one patient and labeled with another name
Improper preparation for test	Fasting indicated, but not followed: fasting glucose, complete lipid panel Pretest medications not administered in the appropriate manner Pretest diet restrictions not met: rare meat ingested before guaiac test
Medication	Medication interfered with testing procedure or by pharmacologic effect: β-agonist can reduce serum potassium concentrations, thiazides can increase serum uric acid levels.
Improper timing of test	Vancomycin trough taken after first dose (rather than before the fourth dose) aPTT measured 2 hours after initial dose (rather than 6 hours after start)
	Fasting glucose test completed shortly after a meal, TSH measured 2 weeks after dose change (rather than 4–6 weeks after change)
Collection incomplete or improper	Abnormal 24-hour urine collection secondary to patient forgetting to void in provided container, blood specimen obtained from extremity with IV infusion site resulting in dilutional effect of glucose, BUN, and electrolytes, specimen collected in incorrect container
Improper handling or	Hyperkalemia because of hydrolysis of blood specimen

storage	
Poor accuracy or precision	Faulty or outdated laboratory reagents in use
Technical	Result incorrectly read, computer keying error
Biologic sex	Many laboratory findings are sex dependent.
Age	Neonatal, pediatric, adult, and geriatric populations have unique reference ranges for numerous laboratory tests.
Pregnancy	Gestational status impacts numerous laboratory findings: alkaline phosphatase, cholesterol, iron, etc.
Posture	Being in upright position during laboratory sampling can increase albumin, calcium, iron, etc.
Exercise	Strenuous exercise before testing can impact lactate, creatine kinase, ALT, AST, uric acid, etc.
Normal physiologic fluctuations	Circadian rhythm can impact cortisol, serum iron, serum creatinine, WBC count, etc.
Medical procedures	Blood transfusion with red blood cells before hemoglobin A_{1c} measured results in normal A_{1c} for poorly controlled individual with diabetes, creatine kinase elevated secondary to recent cardioversion

A_{1c}, hemoglobin A_{1c} (also glycated hemoglobin); ALT, alanine aminotransferase; aPTT, activated partial thromboplastin time; AST, aspartate aminotransferase; BUN, blood urea nitrogen; IV, intravenous; TSH, thyroid-stimulating hormone; WBC, white blood cell.

Test Reliability

As a result of probability, if the same test is completed multiple times on the same sample, typically 1 of 20 results or 5% will be reported outside of the provided reference range. Indicators of test reliability include accuracy, precision, sensitivity, and specificity. Precision refers to the repeatability of a laboratory test (ie, test results fall within a similar value when repeated), whereas accuracy is the ability of a test to provide a result that is reflective of the “true” value

(ie, the test result matches the actual value). Quality control and assurance practices at each laboratory are monitored regularly to ensure reliability of results. Typically, if a result that is significantly outside the reference range is obtained, the laboratory will repeat the test to confirm or refute the finding.

Research studies generally establish the sensitivity and specificity of laboratory tests. Clinically, these are essential to distinguish the presence or absence of a disease or condition. Sensitivity is the ability of the test to correctly identify the disease or condition. If a test is 95% sensitive, then 95% of the individuals will be correctly identified as having the disease or condition, but 5% will have a negative test result even though they have the disease or condition (false negative). Specificity is the ability of the test to rule out individuals who do not have the disease or condition. If a test is 95% specific, then 95% of the individuals without disease will have a correct negative result, but 5% will be identified as having the disease or condition even though they are negative (false positive).

Units of Measure

The International System of Units (SI) reports clinical laboratory values using the metric system. The basic unit of mass for the SI system is the *mole*, which is not influenced by the added weight of salt or ester formulations. Therefore, the mole is technically and pharmacologically more meaningful than is the gram because each physiologic reaction occurs on a molecular level. Efforts to implement the SI system internationally for laboratory test reports have been resisted in the United States. Despite adopting SI transition policies in the late 1980s, major American medical journals have since reverted to the traditional units for laboratory test reporting.[4,5] In this chapter, reference ranges for common laboratory tests are presented in both conventional and SI units, along with "conversion factors" to interchange traditional and SI units (**Tables 2-2** and **2-3**).

Table 2-2
Blood Chemistry Reference Values

Laboratory Test	Normal Reference Values		Conversion Factor	Comments
	Conventional Units	SI Units		
Electrolytes				
Sodium	135–147 mEq/L or mmol/L	135–147 mmol/L	1	Low sodium is usually caused by excess water (eg, ↑ serum antidiuretic hormone) and is treated with water restriction. ↑ in severe dehydration, diabetes insipidus, significant renal and GI losses
Potassium	3.5–5 mEq/L	3.5–5 mmol/L	1	↑ with renal dysfunction, acidosis, K-sparing diuretics, hemolysis, burns, crush injuries. ↓ by diuretics, alkalosis, severe vomiting and diarrhea, heavy NG suctioning
CO_2 content	21–32 mEq/L	21–32 mmol/L	1	Sum of HCO_3^- and dissolved CO_2. Reflects acid–base balance and compensatory pulmonary (CO_2) and renal (HCO_3^-) mechanisms. Primarily reflects HCO_3^-
Chloride	95–110 mEq/L	95–110 mmol/L	1	Important for acid–base balance. ↓ by GI loss of chloride-rich fluid (vomiting, diarrhea, GI suction, intestinal fistulas, overdiuresis)
BUN	8–20 mg/dL	2.8–7.1 mmol/L	0.357	End product of protein metabolism, produced by liver, transported in blood, excreted renally. ↑ in renal dysfunction, high protein intake, upper GI bleeding, volume contraction
Creatinine	≤1.5 mg/dL	≤133 μmol/L	88.4	Major constituent of muscle; rate of formation constant; affected by muscle mass (lower with aging and gender); excreted renally. ↑ in renal dysfunction. Used as a primary marker for renal function (GFR)
CrCl	90–130 mL/minute	1.5–2.16 mL/s	0.01667	Reflects GFR; ↓ in renal dysfunction. Used to adjust dosage of renally eliminated drugs
Estimated GFR	90–120 mL/minute/1.73 m^2	n/a	n/a	Possibly a more accurate reflection of renal function than is CrCl. Still influenced by muscle mass

Homocysteine	4–12 µmol/L	4–12 µmol/L	1	Damages vessel endothelial, which may increase the risk for cardiac disease. Associated with deficiencies in folate, vitamin B_6, and vitamin B_{12}
LDH	100–250 IU/L	1.67–4.17 µkat/L	0.01667	High in heart, kidney, liver, and skeletal muscle. Five isoenzymes: LD1 and LD2 mostly in heart, LD5 mostly in liver and skeletal muscle, LD3 and LD4 are nonspecific. ↑ in malignancy, extensive burns, PE, renal disease
BNP	<100 pg/mL	<100 ng/L	1	BNP >500 ng/L indicates congestive heart failure. Released from ventricles with ↑ workload placed on heart
NT-proBNP	<400 pg/mL	<400 ng/L	1	NT-proBNP >2000 ng/L indicates congestive heart failure.
CRP	0–1.6 mg/dL	0–16 mg/L	10	Nonspecific indicator of acute inflammation. Similar to ESR, but more rapid onset and greater elevation. CRP >3 mg/dL increases risk of cardiovascular disease.
hs-CRP	0–1.0 mg/dL	0–10 mg/L	10	More sensitive measure of CRP
Liver Function				
AST	0–35 IU/L	0–0.58 µkat/L	0.01667	Large amounts in heart and liver; moderate amounts in muscle, kidney, and pancreas. ↑ with MI and liver injury. Less liver specific than is ALT
ALT	0–35 IU/L	0–0.58 µkat/L	0.01667	From heart, liver, muscle, kidney, pancreas. ↑ negligible unless parenchymal liver disease. More liver specific than is AST
ALP	20–130 IU/L	0.33–2.17 µkat/L	0.01667	Large amounts in bile ducts, placenta, bone. ↑ in bile duct obstruction, obstructive liver disease, rapid bone growth (eg, Paget disease), pregnancy
GGT				Sensitive test reflecting hepatocellular injury; not helpful in differentiating liver disorders. Usually high in chronic alcoholics
Male	9–50 IU/L			
Female	8–40 IU/L			
Bilirubin—total	0.1–1 mg/dL	2–18 µmol/L	17.1	Breakdown product of hemoglobin, bound to albumin, conjugated in liver. Total bilirubin includes direct (conjugated) and indirect bilirubin. ↑ with hemolysis, cholestasis, liver injury
Bilirubin—direct	0–0.2 mg/dL	0–4 µmol/L	17.1	
Miscellaneous				
Amylase	35–118 IU/L	0.58–1.97 µkat/L	0.01667	Pancreatic enzyme; ↑ in pancreatitis or duct obstruction
Lipase	10–160 IU/L	0–2.67 µkat/L	0.01667	Pancreatic enzyme, ↑ acute pancreatitis, elevated for a longer period than is amylase
PSA	0–4 ng/mL	0–4 µg/L	1	↑ in BPH and also in prostate cancer. PSA levels of 4–10 ng/mL should be worked up. Risk of prostate cancer increased if free PSA/total PSA <0.25
TSH	0.5–4.7 µIU/mL	0.5–4.7 mIU/L	1	↑ TSH in primary hypothyroidism requires exogenous thyroid supplementation; ↓ TSH in hyperthyroidism
Procalcitonin	<0.5 ng/mL	<0.5 µg/L	1	↑ Bacterial infections—low risk of sepsis if <0.5 ng/mL; high risk of severe sepsis if >2.0 ng/mL

Total cholesterol	<200 mg/dL	<5.2 mmol/L	0.02586	Consult current guidelines.
LDL	<100 mg/dL	<2.58 mmol/L	0.02586	Current guidelines recommend starting moderate- to high-intensity statin therapy based on risk stratification; consult current guidelines.
HDL	Female: >50 mg/dL Male: >40 mg/dL	Female: >1.29 mmol/L Male: >1.03 mmol/L	0.02586	Consult current guidelines.
Triglycerides (fasting)	<150 mg/dL	<1.70 mmol/L	0.0113	↑ by alcohol, saturated fats, drugs. Obtain fasting level. Consult current guidelines.

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BNP, brain natriuretic peptide; BPH, benign prostatic hypertrophy; BUN, blood urea nitrogen; CHF, congestive heart failure; CK, creatine kinase (formerly known as creatine phosphokinase); CrCl, creatinine clearance; CRP, C-reactive protein; cTnI, cardiac troponin I; ESR, erythrocyte sedimentation rate; GFR, glomerular filtration rate; GGT, γ-glutamyl transferase; GI, gastrointestinal; HDL, high-density lipoprotein; IM, intramuscularly; LDH, lactate dehydrogenase; LDL, low-density lipoprotein; MI, myocardial infarction; NG, nasogastric; PE, pulmonary embolism; PSA, prostate-specific antigen; SI, International System of Units; TPN, total parenteral nutrition; TSH, thyroid-stimulating hormone.

Table 2-3
Hematologic Laboratory Values

Laboratory Test	Normal Reference Values		Comments
	Conventional Units	SI Units	
RBC Count			
■ Male	4.3–5.9 × 10^6/μL	4.3–5.9 × 10^{12}/L	
■ Female	3.5–5.0 × 10^6/μL	3.5–5.0 × 10^{12}/L	
Hct			↓ with anemias, bleeding, hemolysis. ↑ with polycythemia, chronic hypoxia
■ Male	40.7%–50.3%	0.4–0.503	
■ Female	36%–44.6%	0.36–0.446	
Hgb			Similar to Hct
■ Male	13.8–17.5 g/dL	138–175 g/L	
■ Female	12.1–15.3 g/dL	121–153 g/L	
MCV	80–97.6 μm^3	80–97.6 fL[a]	Describes average RBC size; ↑ MCV—macrocytic, ↓ MCV—microcytic
MCH	27–33 pg/cell	1.66–2.09 fmol/cell	Measures average weight of Hgb in RBC
MCHC	33–36 g/dL	20.3–22 mmol/L	More reliable index of RBC hemoglobin than is MCH. Measures average concentration of Hgb in RBC. Concentration will not change with weight or size of RBC.
Reticulocyte count (adults)	0.5%–1.5%	0.005–0.015	Indicator of RBC production; ↑ suggests ↑ number of immature erythrocytes released in response to stimulus (eg, iron in iron deficiency anemia)
ESR	0–30 mm/hour	0–30 mm/hour	Nonspecific; ↑ with inflammation, infection, neoplasms, connective tissue disorders, pregnancy, nephritis. Useful monitor of temporal arteritis and polymyalgia rheumatica
WBC count	3.8–9.8 × 10^3/μL	3.8–9.8 × 10^9/L	Consists of neutrophils, lymphocytes, monocytes, eosinophils, and basophils; ↑ in infection and stress
ANC	2000 cells/mμL		ANC − WBC × (% neutrophils + % bands)/100; if <500 ↑ risk infection, if >1000 ↓ risk infection
Neutrophils	40%–70%	0.4–0.7	↑ in neutrophils, suggests bacterial or fungal infection. ↑ in bands, suggests bacterial infection
Bands	0%–10%	0–0.1	
Lymphocytes	22%–44%	0.22–0.44	
Monocytes	4%–11%	0.04–0.11	

Eosinophils	0%–8%	0–0.08	Eosinophils ↑ with allergies, parasitic infections, and certain neoplasms
Basophils	0%–3%	0–0.03	
Platelets	150–450 × 10^3/μL	150–450 × 10^9/L	<100 × 10^3/μL: thrombocytopenia <20 × 10^3/μL: ↑ risk of severe bleeding
Iron			
■ Male	45–160 μg/dL	8.1–31.3 μmol/L	Body stores two-thirds in Hgb; one-third in bone marrow, spleen, liver; only small amount present in plasma. Blood loss major cause of deficiency
■ Female	30–160 μg/dL	5.4–31.3 μmol/L	↑ needs in pregnancy and lactation
■ TIBC	220–420 μg/dL	39.4–75.2 μmol/L	↑ capacity to bind iron with iron deficiency

ANC, absolute neutrophil count; ESR, erythrocyte sedimentation rate; Hct, hematocrit; Hgb, hemoglobin; MCH, mean corpuscular hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; RBC, red blood cell; SI, International System of Units; TIBC, total iron-binding capacity; WBC, white blood cell.

[a]fL, femtoliter; femto, 10^{-15}; pico, 10^{-12}; nano, 10^{-9}; micro, 10^{-6}; milli, 10^{-3}.

FLUIDS AND ELECTROLYTES

Refer to Chapter 27, Fluid and Electrolyte Disorders, for more detailed information.

Sodium

Reference Range: 135–147 mEq/L or mmol/L

Sodium is the predominant cation of the extracellular fluid (ECF), and human cells reside in salt water. Along with chloride, potassium, and water, sodium is important in establishing serum osmolarity and osmotic pressure relationships between intracellular fluid (ICF) and ECF. Osmoregulatory system regulates the plasma sodium concentrations to remain in a normal range by controlling water intake and excretion.[6] An increase in the serum sodium concentration could suggest either impaired sodium excretion or volume contraction. On the contrary, a decrease in the serum sodium concentration to less-than-normal values could reflect hypervolemia, abnormal sodium losses, or sodium starvation. Although healthy individuals are able to maintain sodium

homeostasis without difficulty, patients with kidney failure, heart failure (HF), or lung disease often encounter sodium and water imbalances. In adults, changes in serum sodium concentrations most often represent water rather than sodium imbalance. Therefore, serum sodium concentrations are more reflective of a patient's fluid status rather than of sodium balance. Clinical manifestations of hyponatremia or hypernatremia are mostly neurologic, and rapid changes in serum sodium concentrations can lead to severe and sometimes fatal brain injury.[6]

HYPONATREMIA

Hyponatremia can result from dilution of the sodium concentration in serum or from a total body depletion of sodium. The finding of hyponatremia implies that sodium has been diluted throughout all body fluids because water moves freely across cell membranes in response to oncotic pressures. Hyponatremia can denote low, high, or normal tonicity. Dilutional hyponatremia is the most common form and results from water retention.[7] Some clinical conditions such as cirrhosis, congestive heart failure (CHF), the syndrome of inappropriate antidiuretic hormone secretion (SIADH), and renal impairment, as well as the administration of osmotically active solutes (eg, albumin and mannitol) are commonly associated with dilutional hyponatremia. Drugs that can induce SIADH, thereby causing a reversible hyponatremia (especially in the elderly), include cyclophosphamide, carbamazepine, desmopressin, oxcarbazepine, oxytocin, serotonin selective reuptake inhibitors, and vincristine.[7–9] Hyponatremia that results from sodium depletion presents as a low serum sodium concentration in the absence of edema. Sodium-depletion hyponatremia can be caused by mineralocorticoid deficiencies, sodium-wasting renal disease, or replacement of sodium-containing fluid losses with nonsaline solutions.[7] Therapy with thiazide diuretics may also lead to the development of severe hyponatremia. Hyponatremia is frequently seen in hospitalized patients; however, morbidity varies significantly in severity, and

serious complications can be due to the disorder itself or due to the inappropriate management and rapid correction of the sodium levels.

HYPERNATREMIA

Hypernatremia represents a state of relative water deficiency in relation to the body's sodium stores. Because sodium contributes to the cell's tonicity, hypernatremia denotes hypertonicity and at least transient cellular dehydration.[10] Some of the causes of hypernatremia are loss of free water, loss of hypotonic fluid, or excessive sodium intake. Free water loss is uncommon, except in the presence of diabetes insipidus. Diarrhea is the most common cause of hypotonic fluid loss in infants and the elderly. Increased retention of sodium in patients with hyperaldosteronism can also increase serum sodium concentrations. Excessive salt intoxication is usually accidental or iatrogenic, and most commonly results from inappropriate intravenous (IV) administration of hypertonic salt solutions. Some β-lactam antibiotics (eg, ticarcillin) contain a modest sodium load and can cause fluid overload when high dosages are administered.

The primary defense against hypertonicity is thirst and subsequent fluid intake. Hypernatremic syndromes, therefore, usually occur in patients who are unable to drink sufficient fluids. For example, demented elderly patients are at increased risk because they depend on others for their water requirements. Similarly, patients who are vomiting, comatose, or not allowed oral fluids are at risk for hypernatremia.

Potassium

Reference Range: 3.5–5.0 mEq/L or mmol/L

Potassium is the most abundant intracellular cation in the body responsible for regulating enzymatic function and neuromuscular tissue excitability. Approximately 90% of the total body potassium is found in the ICF, with the majority in skeletal muscle, and only about 10% available in the ECF. The intracellular and extracellular

potassium concentrations are regulated by the sodium–potassium adenosine triphosphatase (Na^+-K^+-ATPase) pump. The potassium ion in the ECF is filtered freely at the glomerulus of the kidney, reabsorbed in the proximal tubule, and secreted into the distal segments of the nephron. Because the majority of potassium is sequestered within cells, a serum potassium concentration is not a good measure of total body potassium. Intracellular potassium, however, cannot be measured easily. Fortunately, the clinical manifestations of potassium deficiency (eg, fatigue, drowsiness, dizziness, confusion, electrocardiographic changes, muscle weakness, and muscle pain) correlate well with serum concentrations. The serum potassium concentration is buffered and can be within normal limits despite abnormalities in total body potassium. During potassium depletion, potassium moves from the ICF into the ECF to maintain the serum concentration. When the serum concentration decreases by a mere 0.3 mEq/L, the total body potassium deficit is ~100 mEq. Serum potassium concentrations, therefore, can be misleading when interpreted in isolation from other considerations, and assumptions should not be made as to the status of total body potassium concentration based solely on a serum concentration measurement. Disorders of potassium are commonly the result of (a) alterations in intake, (b) alterations with excretion, and/or (c) unbalanced transcellular shifting of potassium (eg, metabolic acidosis/alkalosis).

HYPOKALEMIA

The kidneys are responsible for about 90% of daily potassium loss (~40–90 mEq/day), and the remaining 10% of potassium is excreted in the stool and a negligible amount in sweat. The kidneys, however, have only a limited ability to conserve potassium. Even when potassium intake has ceased, the urine will contain at least 5 to 20 mEq of potassium per 24 hours. Therefore, prolonged IV therapy with potassium-free solutions in a patient unable to obtain potassium in foods (eg, nothing by mouth) can result in hypokalemia. Hypokalemia can also be induced by osmotic diuresis (eg, mannitol

and glucosuria), use of thiazide or loop diuretics (eg, hydrochlorothiazide, furosemide, respectively), excessive mineralocorticoid activity, or protracted vomiting. Although the fluid secreted along most of the upper gastrointestinal (GI) tract contains only a modest amount of potassium (ie, 5–20 mEq/L), vomiting can induce hypokalemia because of the combined effect from decreased food intake, loss of acid, alkalosis, and loss of sodium. The loss of large amounts of colonic fluid through severe diarrhea and/or laxative abuse can cause potassium depletion because fluid in the colon is high in potassium content (ie, 30–40 mEq/L). Insulin and stimulation of β_2-adrenergic receptors can also induce hypokalemia because both increase the movement of potassium into cells from the ECF. The magnitude of a potassium deficiency is difficult to establish because of the limited presence of potassium in the ECF. Equation 2-1 can be used to estimate the potassium deficit with hypokalemia:

$$\text{Kdeficit (mmol)} = (K_{\text{normal lower limit}} - K_{\text{measured}}) \times \text{kg of body weight} \times 0.4$$

(Eq. 2-1)

It is also important to note that hypomagnesemia often accompanies hypokalemia, because magnesium is necessary for the shifting of sodium, potassium, and calcium in and out of cells. As a result, individuals with hypokalemia not responding to potassium therapy may be refractory to treatment until hypomagnesemia is corrected. Some laboratories omit magnesium from the general electrolyte panel, so this test may need to be specially ordered.

HYPERKALEMIA

Hyperkalemia most commonly results from decreased renal excretion of potassium (eg, renal failure, renal hypoperfusion, and hypoaldosteronism), excessive exogenous potassium administration, or excessive cellular breakdown (eg, hemolysis, burns, crush injuries, surgery, and infections). Drug-induced causes include angiotensin-converting enzyme (ACE) inhibitors, angiotensin-

receptor blockers (ARBs), aldosterone antagonists, and nonsteroidal anti-inflammatory drugs, to name a few. Metabolic acidosis can also induce hyperkalemia because hydrogen ions move into cells in exchange for potassium and sodium. Abnormal potassium concentrations in the serum primarily affect excitability of nerve and muscle tissue (eg, myocardial tissue). As a result, arrhythmias can be induced by hyperkalemia or hypokalemia. Potassium also affects some enzyme systems and acid–base balance, as well as carbohydrate and protein metabolism.

Carbon Dioxide Content

Reference Range: 21–32 mEq/L or mmol/L

The carbon dioxide (CO_2) content in the serum represents the sum of bicarbonate (HCO_3^-) and dissolved CO_2 concentrations. The dissolved CO_2 represents a relatively small component of total CO_2 content, making CO_2 essentially a measure of the serum bicarbonate. Chloride and bicarbonate are the primary negatively charged anions that offset the positively charged cations (ie, sodium and potassium). CO_2 is a waste product that is produced after we burn food for energy. Healthy individuals are able to maintain CO_2 in an appropriate range. A CO_2 level below the reference range is associated with such conditions as diabetic ketoacidosis, Addison disease, and metabolic acidosis. A CO_2 level above the reference range is associated with dehydration, Cushing syndrome, and metabolic alkalosis.

Although several buffer systems (eg, hemoglobin [Hgb], phosphate, and protein) participate in regulating pH within physiologic limits, the carbonic acid–bicarbonate system is the most important. From a clinical standpoint, most disturbances of acid–base balance result from imbalances of the carbonic acid–bicarbonate system. The importance of bicarbonate in maintaining physiologic pH is presented in Chapter 26, Acid–Base Disturbances.

Chloride

Reference Range: 95–110 mEq/L or mmol/L

Chloride (Cl^-) is the principal inorganic anion of the ECF; changes in chloride concentration are usually related to sodium concentration in an effort to maintain a neutral charge. Serum chloride has no real diagnostic significance. The relationship between serum concentrations of sodium, bicarbonate, and chloride is described by Eq. 2-2, where *R* represents the anion gap (AG):

$$Cl^- + HCO_3^- + R = Na^+ \quad \textbf{(Eq. 2-2)}$$

As with bicarbonate, chloride contributes to maintaining acid–base balance. A decreased serum chloride often accompanies metabolic alkalosis, whereas an increased serum chloride may indicate a hyperchloremic metabolic acidosis. The serum chloride, however, can also be slightly decreased in acidosis if organic acids or other acids are the primary cause of the acidosis. *Hyperchloremia*, absence of metabolic acidosis, is seldom encountered because chloride retention is usually accompanied by sodium and water retention. *Hypochloremia* can result from excessive GI loss of chloride-rich fluid (eg, vomiting, diarrhea, gastric suctioning, and intestinal fistulas). Because chloride ions are excreted with cations by the kidneys, hypochloremia may also result from significant diuresis.

Anion Gap

Reference Range: 7–16 mEq/L or mmol/L

The R factor, or AG, represents the contribution of unmeasured acids, such as lactate, phosphates, sulfates, and proteins. As displayed in Eq. 2-2, a patient's AG is determined by subtracting the primary anions (Cl^- and HCO_3^-) from the primary cation (Na^+). Some clinicians include potassium in this determination and subtract the anions from both major cations (Na^+ and K^+). If potassium is not incorporated in the calculation, a normal AG is typically 5 to 12

mEq/mL. If potassium is considered, a normal AG would be <16 mEq/mL.

An elevated AG may be indicative of metabolic acidosis caused by an increase in lactic acids, ketoacids, salicylic acids, methanol, or ethylene glycol. A low AG may be the result of reduced concentrations of unmeasured anions (eg, hypoalbuminemia) or from systematic underestimation of serum sodium (eg, hyperviscosity of myeloma). See Chapter 26, Acid–Base Disturbances, for a more detailed discussion of the clinical use of the AG.

Blood Urea Nitrogen

Reference Range: 8–20 mg/dL or 2.8–7.1 mmol/L

Urea nitrogen is a waste product that comes from protein breakdown. It is produced solely by the liver, transported in the blood, and excreted by the kidneys. The serum concentration of urea nitrogen (ie, blood urea nitrogen [BUN]) is reflective of renal function because the urea nitrogen in the blood is filtered completely at the glomerulus of the kidney and then reabsorbed and tubularly secreted within nephrons. Acute or chronic renal failure is the most common cause of an elevated BUN. Although the BUN is an excellent screening test for renal dysfunction, it does not sufficiently quantify the extent of renal disease. In addition, several nonrenal factors such as unusually high protein intake, disease states that increase protein catabolism (or upper GI bleeding), and glucocorticoid therapy can increase the BUN concentration. Liver disease and a low protein diet can lead to a lower BUN concentration. A patient's hydration status will also influence BUN; a water deficit tends to concentrate the urea nitrogen, and a water excess dilutes the urea nitrogen. The ratio of BUN to serum creatinine (SCr) can also be of clinical use. A normal ratio is roughly 15:1. Ratios >20:1 are observed in patients with decreased blood flow to the kidney (eg, prerenal disease such as dehydration or conditions involving reduced cardiac output) or conditions involving increased protein in the blood (eg, dietary intake

or an upper GI bleed). Situations in which the BUN:SCr ratio is <15:1 are seen in patients with renal failure, significant malnourishment (decreased intake of protein), or severe liver disease in which the liver is no longer able to form urea. It is important to note that BUN can change independent of the renal function, and, therefore, SCr is more useful in estimating renal function.

Creatinine

Reference Range: ≤1.5 mg/dL or ≤133 µmol/L

Creatinine is derived from the creatine and phosphocreatine metabolism in the skeletal muscle. Its rate of formation for a given individual is remarkably constant and is determined primarily by an individual's muscle mass or lean body weight. Therefore, the SCr concentration is slightly higher in muscular subjects, but, unlike the BUN, it is less directly affected by exogenous factors or liver impairment. Once creatinine is released from muscle into plasma, it is excreted renally almost exclusively by glomerular filtration and is not reabsorbed or metabolized by the kidney. A decrease in the glomerular filtration rate (GFR) results in an increase in the SCr concentration. Thus, careful interpretation of the SCr concentration is used widely in the clinical evaluation of patients with suspected renal disease. However, SCr concentration on its own should not be utilized to assess the level of kidney function in an individual.

A doubling of the SCr level roughly corresponds to a 50% reduction in the GFR. This general rule of thumb only holds true for steady-state creatinine levels.[11]

Of importance, as patients become older, there is a reduction in muscle mass and creatinine production is progressively decreased. Furthermore, the SCr concentration in female patients is generally 0.2 to 0.4 mg/dL (85%–90%) less than that for males because females have less muscle mass.

Creatinine Clearance

Reference Range: 90–130 mL/minute

Because creatinine is cleared almost exclusively through the glomerulus in the kidney, creatinine clearance (CrCl) can be used as a clinically useful measure of a patient's GFR. CrCl serves as a valuable clinical parameter because many renally eliminated drugs are dose adjusted based on the patient's renal function. To determine actual CrCl, the patient's urine is collected for a 24-hour period, and the concentration of urine creatinine (mg/dL), total volume of urine collected during the 24-hour period (mL/minute), and SCr (mg/dL) are determined. The patient-specific measured CrCl is determined using Eq. 2-3:

$$\mathrm{CrCl} = \mathrm{U}_{\mathrm{creatinine}} \times \mathrm{U}_{\mathrm{volume}} / \mathrm{SCr} \times \mathrm{Time\ (minutes)} \quad \textbf{(Eq. 2-3)}$$

Unfortunately, urine collections are time-consuming and expensive, and incomplete collections can substantially underestimate renal function. In lieu of measuring actual CrCl, simplistic equations are commonly used to estimate a patient's CrCl. The following Cockcroft–Gault formula incorporates age, body weight, and SCr.[12] This formula can be utilized to estimate renal function when SCr is stable. Typically, clinicians use ideal body weight (IBW) in the calculation of estimated CrCl; however, actual body weight (ABW) may be used when ABW is less than IBW. For obese patients who are >20% to 30% of their IBW, an adjusted body weight (0.4 [ABW − IBW] + IBW) should be used.[13] Equation 2-4 has the highest correlation and the greatest accuracy in patients with SCr concentrations <1.5 mg/dL[14]:

$$\text{Estimated CrCl for males (mL/minute)} = (140 - \text{Age})\ (\text{body weight in kg}) / (72)(\mathrm{SCr}_{(\mathrm{mg/dL})}) \quad \textbf{(Eq. 2-4)}$$

The Cockcroft–Gault formula must be multiplied by 85% to calculate CrCl for females to account for the fact that females have less muscle mass.

Another commonly used approach to estimating CrCl is the Jelliffe method,[14] shown in Eq. 2-5:

$$\text{Estimated CrCl for males (mL/minute/1.73 m}^2) = 98 - [(0.8)(\text{Age} - 20)]/ (\text{SCr}_{(\text{mg/dL})}) \quad \text{(Eq. 2-5)}$$

This Jelliffe formula must be multiplied by 90% to calculate the CrCl for females. The use of this method substantially underestimates CrCl for patients with SCr values <1.5 mg/dL,[15] whereas Cockcroft–Gault appears to have the highest correlation and greatest accuracy in patients with SCr values <1.5 mg/dL.[14] For patients with liver dysfunction, all methods of calculating CrCl from an SCr value are associated with significant overpredictions of CrCl.[16] Thus, methods for predicting CrCl should be used cautiously when attempting to adjust drug dosages in patients with liver disease. These equations should not be utilized in patients with rapidly changing GFR (eg, acute kidney injury) because they will not provide accurate estimates of the GFR.

CASE 2-1

QUESTION 1: A 24-hour CrCl determination was ordered for D.B., a 72-year-old, 136.69-pound (62-kg) White male. The following data were returned from the clinical laboratory (total collection time was 24 hours):

Total urine volume: 1000 mL
Urine creatinine concentration: 42 mg/dL
SCr: 2.0 mg/dL

What are the measured and the estimated CrCl for D.B. based on the given data?

Using Eq. 2-3, D.B. has a 24-hour measured CrCl of ~15 mL/minute. His estimated CrCl is 29.2 mL/minute using the Cockcroft–Gault method (Eq. 2-4). Based on both methods, D.B.'s ability to clear renally eliminated drugs is impaired, and adjustments to the dose/frequency will need to be made. An incomplete collection of urine during the 24-hour period or possible mishandling of the specimen can be explanations for the lower value seen with the measured CrCl. Because D.B. had an elevated SCr of 2.0 mg/dL, the accuracy of the Cockcroft–Gault estimation might also be

compromised. D.B.'s baseline SCr will need to be established, and if it is determined that SCr of 2.0 mg/dL is corresponding with his baseline, then the Cockcroft–Gault estimation will hold true; if SCr of 2.0 mg/dL represents an acute change, then the Cockcroft–Gault equation should not be used to estimate renal function in D.B.

Estimated Glomerular Filtration Rate

An alternative approach to the Cockcroft–Gault method of estimating an adult patient's clearance was developed as part of the Modification of Diet in Renal Disease (MDRD) study and has been referred to as the MDRD equation.[17] The originally described equation has been modified into an abbreviated format (Eq. 2-6), as follows:

$$\text{Estimated GFR}_{(\text{mL/minute/1.73 m}^2)} = 186 \times (\text{SCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American}) \quad \textbf{(Eq. 2-6)}$$

where SCr is the serum creatinine in mg/dL, age is in years, and the appropriate additional components are included for female or African American patients. Equation 2-6 is applicable to laboratories reporting SCr values that have not been standardized. Starting in 2005, laboratories began standardizing their SCr values using an isotope dilution mass spectrometry to minimize the variation observed in SCr results from different clinical laboratories. In settings in which the SCr results have been standardized, the initial parameter in the MDRD equation is adjusted downward. The following is used to estimate GFR:

$$\text{Estimated GFR}_{(\text{mL/minute/1.73 m}^2)} = 175 \times (\text{SCr})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American}) \quad \textbf{(Eq. 2-7)}$$

When compared with the Cockcroft–Gault approach, MDRD estimations of GFR were more consistent with actual measurements of GFR. However, because both approaches rely on SCr, the influence of muscle mass and dietary intake still must be taken into consideration. In certain patient populations (eg, obese and elderly patients), use of the MDRD can be less accurate, because the MDRD study equation was primarily derived from White subjects with a mean age of 51 years who had nondiabetic renal disease. It is important to note that recent evidence supports removing the race multiplier in the MDRD equation because it may overestimate renal function in patients designated as African American.[18] Although this may increase the prevalence and severity staging of chronic kidney disease (CKD), removal of the race multiplier can increase access to specialists, kidney transplant services, and medical nutrition therapy. It may also promote the early use of pharmacotherapies known to delay kidney progression (eg, ACE inhibitors, ARBs) and prompt dose reductions and/or discontinuation of drugs unknown to be nephrotoxic.[19] A more detailed description of the MDRD equation to estimate GFR is addressed in Chapter 28, Chronic Kidney Disease.

Cystatin C

Reference Range: ≤1.0 mg/L or ≤0.749 mmol/L

Although SCr has long been the gold standard for assessing renal function, cystatin C is a newer biomarker that has been shown to be subject to less biologic variability and more sensitive to early declines in kidney function.[20] Reference ranges for cystatin C are similar to that of SCr (≤1.0 mg/L). But unlike SCr, which is produced from muscle cells, cystatin C is produced by the blood cells and is not appreciably influenced by factors such as muscle mass, diet, age, biologic sex, and race; however, higher levels of cystatin C have been observed in males and patients with higher height and weight, and higher lean body mass. It has also been observed that cystatin C levels are increased with age.[21] Cystatin C is cleared predominantly through the kidneys and is not reabsorbed. Elevated

levels are observed in patients with declining renal function. Elevations in serum cystatin C levels tend to occur earlier than do increases in SCr, which do not tend to rise until ~50% of kidney function is lost, and make it possible to detect renal insufficiency in patients at an earlier stage.[22] This is particularly desirable in patients with diabetes, hypertension, or cardiovascular disease who may be at higher risk for the development of renal disease.

Glucose

Reference Range: 65–115 mg/dL or 3.6–6.3 mmol/L (fasting)

The glucose concentration in the ECF is tightly regulated by homeostatic mechanisms to provide tissues and cells with a reliable source of energy. Two endocrine hormones, insulin and glucagon, work synergistically to maintain normal glucose concentrations. Insulin is released from pancreatic β cells to lower blood glucose concentrations, whereas glucagon (released from the pancreatic α cells), along with the counterregulatory hormones, epinephrine, cortisol, and growth hormone, raises glucose levels. Because plasma glucose concentrations fluctuate in response to ingestion of meals, most glucose concentrations are measured in either the fasting or the postprandial state, depending on the type of information desired. Generally, normal glucose values refer to the plasma glucose concentration in the fasting state. The specific laboratory assay of blood sugar determinations must also be considered because different assay methods vary in their specificity and sensitivity to glucose. Glucose testing using whole blood from capillary finger sticks (eg, self-monitoring of blood glucose) is used in conjunction with blood glucose monitoring devices for patients with diabetes. Because glucometer results rely on enzymatic reactions, results can potentially be altered by oxygen saturation, temperature, and interfering substances (eg, acetaminophen, ascorbic acid).[23] Whole blood measurements using these devices are typically 10% to 15% lower than are corresponding plasma glucose levels. Newer technologies such as continuous glucose monitors (CGMs) measure

interstitial glucose rather than capillary blood samples to estimate plasma glucose levels.The accuracy of these monitors is believed to lead to a clinically and statistically significant decline in both A_{1c} and hypoglycemia.[24]

GLYCATED HEMOGLOBIN

Reference Range: 3.8%–6.4%

Hgb is the oxygen-carrying component of the red blood cell (RBC). During the functional life span of RBCs (~4 months), glucose molecules irreversibly bind to Hgb, which results in glycated HgbA_{1c} (A_{1c}). The concentration of A_{1c} reflects a patient's average blood glucose concentration for the life span of circulating RBCs. As a result, measurement of A_{1c} concentrations is useful to diagnose diabetes, monitor disease progression, and/or assess the efficacy of drug therapy. In a patient without diabetes, about 5% of Hgb is glycated. To diagnose diabetes, two confirmatory A_{1c} ≥6.5% are needed.[25] Of note, point-of-care (POC) A_{1c} testing is generally not recommended for diagnostic purposes because of concerns about standardization and accuracy. Use of POC testing is limited to assessment of glycemic control in the clinic setting.[22] In situations when the A_{1c} is deemed unreliable because of changes in cell turnover (eg, sickle cell anemia, hemodialysis, and pregnancy), plasma glucose testing should be used for diagnosis.[22] Both fasting plasma glucose (FPG) and postprandial glucose contribute variably to the A_{1c} measurement. One study suggests that the higher the A_{1c} (>8.5%), the greater the contribution of FPG to the A_{1c}.[26] As such, the contribution of FPG decreases as the A_{1c} decreases. The American Diabetes Association suggests that an A_{1c} of 7% correlates to an estimated average glucose (eAG) of 154 mg/dL. eAG can be calculated using the following equation: eAG (mg/dL) − (28.7 − A_{1c}) − 46.7.[25] It has been estimated that for every 1% reduction in A_{1c}, the risk of microvascular complications is reduced by 37% and the risk of acute myocardial infarction (MI) by 14%.[27]

HYPERGLYCEMIA AND HYPOGLYCEMIA

Hyperglycemia and hypoglycemia are nonspecific signs of abnormal glucose metabolism. Diabetes mellitus is the most common cause of hyperglycemia along with suboptimal use of insulin and/or other antidiabetic agents, high carbohydrate dietary intake, physical inactivity, recent illness or infection, and increased emotional stress. Hyperglycemia may be caused or worsened by certain medications such as corticosteroids, niacin (doses >2 g/day), thiazide and loop diuretics, protease inhibitors, atypical antipsychotics, and 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins). Insufficient carbohydrate intake because of a missed meal is the most common cause of hypoglycemia in a patient receiving insulin or another hypoglycemic medication. In addition to insulin, drug-induced hypoglycemia includes insulin secretagogues, fluoroquinolone antibiotics, and select herbal products (eg, ginseng, bitter melon, and cinnamon).

CASE 2-2

QUESTION 1: T.C., a 68-year-old male, visits his primary care provider to assess control of his type 2 diabetes. His average blood sugar over the past 90 days recorded by his blood glucose monitor is 195 mg/dL. However, T.C.'s A_{1c} is 9%, which correlates with an eAG of 240 mg/dL. T.C. is confused that these values are different because he routinely ensures his blood glucose machine is calibrated and coded properly.

Why is the laboratory average different?

T.C. should not be alarmed by the difference in these values. His blood glucose monitor is likely working properly and adequately measuring his plasma glucose concentrations. However, the monitor may be reflecting a lower average glucose concentration because of the timing of his daily testing for glucose. For example, measuring blood glucose in a fasting state more frequently than after mealtime could contribute to lower average concentrations because fasting values are typically lower than are postprandial concentrations. The A_{1c} is more indicative of his average blood sugar control during the

past 90 days than the 90-day average recorded by his blood glucose monitor.

Refer to Chapter 53, Diabetes Mellitus, for more detailed information regarding glucose and $HgbA_{1c}$.

Osmolality

Reference Range: 280–300 mOsm/kg or mmol/kg

The osmolality of a solution is a measure of the number of osmotically active ions (ie, particles present) per unit of solution. It is the total number of particles in the solution, not the weight of the particle or the nature of the particle that determines osmolality. Because 1 mole of a substance contains 6×10^{23} molecules, equimolar concentrations of all substances in the undissociated state exert the same osmotic pressure. A mole of an ionized compound such as Na^+Cl^- contributes twice as many particles in solution as 1 mole of an undissociated compound such as glucose. In most situations, the primary determinants of serum osmolality in the ECF are sodium (and its accompanying anions), glucose, and BUN. If one corrects for the concentrations of glucose and BUN, the serum concentration of sodium closely mirrors the serum osmolality. A useful formula (Eq. 2-8) is as follows:

$$\text{Osmolality} = (2 \times \text{Na}^+) + (\text{Glucose}/18) + (\text{BUN}/2.8) \quad \textbf{(Eq. 2-8)}$$

Serum osmolality is helpful when evaluating fluid and electrolyte disorders, particularly sodium imbalances. The difference between the measured serum osmolality and the calculated serum osmolality is commonly referred to as the *osmol gap*. Note that, in practice, osmolality and osmolarity are often used interchangeably. The reader is referred to Chapter 27, Fluid and Electrolyte Disorders, for a more detailed discussion of osmolality.

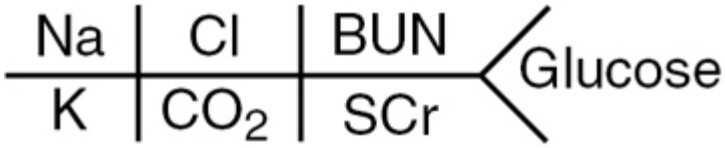
MULTICHEMISTRY PANELS

Frequently, multiple laboratory tests are needed for a given patient. Common clinical laboratory panels include a basic metabolic panel (BMP), comprehensive metabolic panel, electrolyte, hepatic function, and renal function panels (**Table 2-4**). Clinicians will often use the following abbreviated method to report a BMP in written medical records:

Table 2-4
Common Multichemistry Panels

Laboratory Panels	Electrolyte	BMP	CMP	Hepatic	Renal
Sodium	✓	✓	✓		✓
Potassium	✓	✓	✓		✓
Chloride	✓	✓	✓		✓
CO_2	✓	✓	✓		✓
Glucose		✓	✓		✓
Creatinine		✓	✓		✓
BUN		✓	✓		✓
Calcium		✓	✓		✓
Phosphorous					✓
Albumin, total			✓	✓	✓
Total protein			✓	✓	
Alkaline phosphatase (ALP)			✓	✓	
Alanine aminotransferase (ALT, SGPT)			✓	✓	
Aspartate aminotransferase (AST, SGOT)			✓	✓	
Bilirubin, total			✓	✓	
Bilirubin, direct				✓	

BMP, basic metabolic panel; BUN, blood urea nitrogen; CMP, comprehensive metabolic panel; SGOT, serum glutamic:oxaloacetic transaminase; SGPT, serum glutamic:pyruvic transaminase.



Multichemistry tests have become routinely used because they quickly provide basic information concerning organ function at a relatively low cost. In addition, laboratory automation frequently makes it more cost effective to order a battery of tests within a panel versus a single test. A potential disadvantage of obtaining a battery

of tests, however, is that clinicians may be inclined to pursue further laboratory testing when “abnormalities” are not clinically relevant. It is important to note that the individual laboratory tests included in a particular multichemistry panel may vary among clinical laboratories.

Calcium

Reference Range: 8.6–10.3 mg/dL or 2.2–2.74 mmol/L

Calcium has two key physiologic functions within our body; it is an essential intracellular messenger in cells and tissues and a key component of hydroxyapatite, which provides strength, rigidity, and elasticity to the skeleton. All calcium in the body resides primarily in the skeleton, with only about 1% freely exchangeable with that in the ECF. This reservoir of calcium in bones maintains the concentration of calcium in the plasma constant despite pronounced changes in the external balance of calcium. If the homeostatic factors (ie, parathyroid hormone, vitamin D, and calcitonin) that regulate the calcium content of body fluid are intact, a patient can lose 25% to 30% of total body calcium without a change in the concentration of calcium ions in the plasma. Alterations in serum calcium concentrations may have a significant impact on a patient’s renal, GI, and neurologic function. Hypercalcemia is associated with a malignancy, use of thiazide diuretics, hyperthyroidism, and renal failure. Hypocalcemia may indicate a presence of vitamin D deficiency, hypothyroidism, rhabdomyolysis, and CKD.[28] About 40% of the calcium in the ECF is bound to plasma proteins (especially albumin); 5% to 15% is complexed with phosphate and citrate; and about 45% to 55% is in the unbound, ionized form. Most laboratories measure the total calcium concentration; however, it is the free, ionized calcium concentration that is important and closely regulated physiologically. Most laboratories are also able to measure the ionized form of calcium, which has a reference range of 4.5 to 5.6 mg/dL (1.13–1.4 mmol/L). Ionized calcium measures free calcium; however, it is not routinely ordered.[28] It is important to obtain an

albumin level in patients to calculate a corrected calcium level that would account for hypoalbuminemia.

CASE 2-3

QUESTION 1: P.M. is a 61-year-old male admitted status post (s/p) fall because of alcohol intoxication. He has no known drug allergies. P.M.'s past medical history is significant for alcohol-induced seizures, alcohol abuse × 20 years, and hypertension. P.M.'s laboratory tests revealed the following:

Albumin: 2.0 g/dL
Ca: 6.8 mg/dL
Total bilirubin: 10.8 mg/dL
Serum aspartate aminotransferase (AST): 280 IU/L
Alkaline phosphatase: 240 IU/L

Would P.M. be considered hypocalcemic, and how should he be managed?

This case presentation provides insufficient patient data to make a conclusion concerning treatment. However, it does illustrate the importance of treating the patient as a whole, not as a specific laboratory value. Because calcium in the serum is partially bound to plasma proteins (mostly albumin), the serum calcium concentration is affected by the concentration of these plasma proteins. If the albumin concentration is low, the reported serum calcium will generally be less than the lower limit of normal. A useful method to estimate a corrected value for serum calcium in the presence of low serum albumin is to use the following guideline: the total serum calcium will decrease by 0.8 mg/dL for each decrease of 1.0 g/dL in serum albumin concentration. Thus, evaluating P.M.'s corrected calcium is indicated: $(4 - \text{albumin}_{\text{patient}} \times 0.8) + \text{calcium} - \text{corrected calcium}$. For P.M., his "corrected" serum calcium is 8.4 mg/dL, which is just below the reference range, and probably does not warrant treatment with calcium supplementation unless his serum calcium continues to decline. Direct measurement of ionized calcium is independent of albumin concentration, making it unnecessary to correct calcium concentrations in the presence of hypoalbuminemia.

Unfortunately, some clinical laboratories do not have the capability of measuring ionized calcium.

Magnesium

Reference Range: 1.3–2.2 mEq/L or 0.65–1.1 mmol/L

Magnesium is primarily an intracellular electrolyte principally stored in bone and, together with potassium and calcium, helps maintain a neutral charge within the cell. Magnesium also serves an important metabolic role in the phosphorylation of adenosine triphosphate (ATP). Magnesium is necessary for the formation of bone and teeth and for normal nerve and muscle function.

A primary cause of hypomagnesemia is malnourishment. Some other factors associated with hypomagnesemia are the use of proton-pump inhibitors, chronic diarrhea, alcoholism, and diuretic use. Toxemia in pregnancy is associated with hypomagnesemia. Hypomagnesemia needs to be corrected before attempting to correct hypokalemia or hypocalcemia. Attempts to replace potassium or calcium in patients with hypomagnesemia will be ineffective until the low magnesium concentrations are adequately addressed. Excessive ingestion of magnesium-containing antacids can lead to hypermagnesemia. Increased concentrations of magnesium are also observed in patients with reduced renal function. Hypermagnesemia can slow conduction in the heart, prolong PT intervals, and widen the QRS complex.

Phosphate

Reference Range: 2.5–5 mg/dL or 0.80–1.6 mmol/L

The extracellular concentration of phosphate as inorganic phosphorus is the prime determinant of the intracellular concentration, which in turn is the source of phosphate for ATP and phospholipid synthesis. Intracellular phosphate is also important in the regulation of nucleotide degradation.

The ECF concentration of phosphate is influenced by parathyroid hormone, intestinal phosphate absorption, renal function, bone metabolism, and nutrition. Moderate hypophosphatemia is encountered by malnourished patients (especially when anabolism is induced), patients who excessively use antacids (aluminum-containing antacids bind phosphorus in the GI tract), chronic alcoholics, and patients with sepsis. Clinical consequences of severe hypophosphatemia involve nervous system dysfunction, muscle weakness, rhabdomyolysis, cardiac irregularities, and dysfunction of leukocytes and erythrocytes. Hyperphosphatemia is most commonly caused by renal insufficiency, although increased vitamin D, hypoparathyroidism, and advanced malignancies are also significant causes.

Uric Acid

Reference Range: 3–8 mg/dL or 179–476 µmol/L

Uric acid is an end product of the metabolic breakdown of purines. It is commonly referred to as a *metabolically inert compound* offering little biologic utility. The renal system is responsible for 60% to 70% of total body uric acid excretion. Most uric acid is freely filtered, with ~90% reabsorbed via the nephron.

Increased serum uric acid concentrations can result from either a decrease in urate excretion (eg, renal dysfunction, competition with drugs using the same transporters for elimination [thiazide diuretics, niacin]) or excessive urate production (eg, increased purine metabolism resulting from cytotoxic therapy of neoplastic or myeloproliferative disorders). Gout, a common arthritic condition characterized by hyperuricemia, is usually associated with increased serum concentrations of uric acid along with deposits of monosodium urate crystals in joints. Low serum uric acid concentrations are inconsequential, and are usually reflective of drugs that have hypouricemic activity (eg, high dosages of salicylates).

PROTEINS

Prealbumin

Reference Range: 19.5–35.8 mg/dL or 195–358 mg/L

Prealbumin is an important serum protein, but in comparison with other proteins, it accounts for a relatively small percentage of all circulating proteins. It is also referred to as thyroxine-binding prealbumin owing to its role as a transport mechanism for triiodothyronine (T_3) and thyroxine (T_4). However, it is most frequently used to monitor patients at risk for poor nutrition (eg, patients with eating disorders, patients with human immunodeficiency virus, or patients receiving total parenteral nutrition). Compared with the long half-life of albumin (about 3 weeks), the half-life of prealbumin is only 1 to 2 days. This shorter half-life provides a more accurate reflection of acute changes in protein synthesis, catabolism, and, ultimately, immediate nutrition status. Hepatic disease and malnutrition are associated with decreases in prealbumin (and albumin). Hodgkin lymphoma, pregnancy, CKD, and corticosteroid use can increase prealbumin serum concentrations.

Albumin

Reference Range: 3.6–5 g/dL or 36–50 g/L

Albumin, produced by the liver, contributes ~80% to serum colloid osmotic pressure. As a result, hypoalbuminemic states are commonly associated with edema and third spacing of ECF. A lack of essential amino acids from malnutrition or malabsorption, or impaired albumin synthesis by the liver, can result in decreased serum albumin concentrations. Most forms of hepatic insufficiency are associated with decreased synthesis of albumin. It can be lost directly from the blood because of hemorrhage, burns, or exudates or it may be lost directly into the urine because of nephrosis. Serum albumin concentrations seldom increase, but increases may be

noted in volume depletion, in shock, or immediately after the administration of large amounts of IV albumin. In addition to its diagnostic value, albumin concentration is an important consideration in the therapeutic monitoring of drugs and electrolytes that are highly protein bound (eg, phenytoin, digoxin, and calcium). In cases of severe hypoalbuminemia, determination of the “free” or unbound concentration of these entities might be necessary for an accurate assessment of drug therapy.

Globulin

Reference Range: 2.3–3.5 g/dL or 23–35 g/L

In addition to albumin, globulin is another primary plasma protein. Albumin principally functions to maintain serum oncotic pressure, whereas globulins play an active role in immunologic processes. The globulins can be separated into several subgroups such as α, β, and γ. The γ-globulins can be separated further into various immunoglobulins (Igs; eg, IgA, IgM, and IgG). Chronic infection or rheumatoid arthritis can increase Ig levels, and fractionation of Igs can provide useful information in the evaluation of immune disorders. Because globulin is not manufactured solely by the liver, the ratio of albumin to globulin (the A/G ratio) is changed in patients with liver disease. Changes in this ratio result from decreased albumin concentration and a compensatory increase in globulin concentration.

CARDIAC MARKERS

Cardiac biomarkers are useful for the evaluation, diagnosis, and monitoring of patients with suspected heart damage. These markers, which include some enzymes, are often released into the blood when the myocardium becomes damaged or dies. Enzyme activity is typically expressed in terms of international units (IUs), where 1 IU is the enzyme amount needed to catalyze the conversion of 1 μmol of

substrate per minute. The analogous expression in SI terms involves the term katal (kat). One katal is the amount of enzyme to catalyze 1 mole of substrate per second, making 1.0 µkat the amount for 1.0 µmol/second. Based on this information, the conversion between µkat and IU is 1 µkat—60 IU.

Creatine Kinase

Reference Range: Female, 20–170 IU/L or 0.33–2.83 µkat/L; Male, 30–220 IU/L or 0.5–3.67 µkat/L

Creatine kinase (CK) catalyzes the transfer of high-energy phosphate groups in tissues that consume large amounts of energy (eg, skeletal muscle, myocardium, and brain). The serum concentration of CK can be increased by strenuous exercise, intramuscular injections of tissue-irritating drugs (eg, diazepam and phenytoin), crush injuries, myocardial damage, rhabdomyolysis, or high doses of certain HMG-CoA reductase inhibitors.

CK is composed of M and B subunits and is divided into three isoenzymes: MM, BB, and MB. The CK-MM isoenzyme is found predominantly in skeletal muscle, the CK-BB is predominantly in the brain, and the CK-MB is predominantly in the myocardium. Myocardial CK activity consists of 80% to 85% CK-MM and 15% to 20% CK-MB. Noncardiac tissues that contain large amounts of CK have either CK-MM or CK-BB. The MB fraction is rare in tissues other than in the myocardium, making it a more specific cardiac marker.

CK-MB typically begins to increase 3 to 6 hours after an acute MI, peaks at 12 to 24 hours, and accounts for about 5% or more of the total CK.[29] Myocardial damage appears to correlate with the amount of CK-MB released into the serum (ie, the higher the amount of CK-MB, the more extensive the myocardial injury). Although CK-MB levels >25 IU/L are usually associated with an MI, the absolute amount can vary, depending on the assay method.[30] Generally, if the amount of CK-MB exceeds 6% of the total CK, myocardial injury has

presumably occurred. Analysis of CK-MB provides a rapid, sensitive, specific, cost effective, and definitive means of detecting MI.[31]

Troponin

Reference Range: Cardiac Troponin T (cTnT) 0–0.1 ng/mL or µg/L; Cardiac Troponin I (cTnI) 0–0.3 ng/mL or µg/L; High-Sensitivity Cardiac Troponin T (hs-cTnT) 0–14 ng/L; High-Sensitivity Cardiac Troponin I (hs-cTnI) 0–6 ng/L

Troponins are proteins that regulate the calcium-mediated interaction of actin and myosin within muscles. There are two cardiac-specific troponins, cardiac troponin I (cTnI) and cardiac troponin T (cTnT). cTnT is present in cardiac and skeletal muscle cells, whereas cTnI is present only in cardiac muscle.[32,33] Although compared with the detection of CK-MB, the presence of cTn is a more sensitive and specific indicator of myocardial necrosis,[34] it should be noted that other conditions can cause an elevation in cTn (cardiac, renal, pulmonary, etc). The concentration of cTn increases within 2 to 5 hours of an acute MI. On average, troponin remains elevated for about 10 days compared with the 2- to 3-day elevation typically observed with CK-MB. cTnI levels >0.3 ng/mL and cTnT levels >0.1 ng/mL are suggestive of acute myocardial tissue necrosis, but these values may vary slightly by assay (because of lack of standardization) and by institution. High-sensitivity cardiac troponin (hs-cTn) can be employed for rapid MI rule-out or rule-in.[35] Hs-cTn can measure cTn at much lower concentrations than do older conventional assays. There are several methods for MI rule-out using these assays. One such method is the 0/2 method; an hs-cTn should be drawn on arrival (0h) and again 2 hours later (2h).[35,36] These lab values are used in conjunction with all relevant clinical data (eg, electrocardiogram [ECG], validated risk scores, and past and current comorbid conditions) to help rule out MI. To be considered a rule-out using the hs-cTnT, the levels at 0h and 2h should be <14 ng/L and change from baseline at 2h should be <4 ng/L.[35,36] Using the hs-cTnI, the 0h and 2h levels should be <6 ng/L,

and the change from baseline should be <2 ng/L.[35] Patients who present and do not completely fit the abovementioned criteria may require a third hs-cTn lab test to confirm rule out. For rapid MI rule-in, the patient would need to present with an hs-cTnT ≥53 ng/mL or hs-cTnI ≥64 ng/L or have a change in hs-cTnT ≥10 ng/L or hs-cTnI ≥15 ng/L at 2h.[35] Owing to differences in heart mass, estrogen levels, and so on, females have lower baseline levels of circulating hs-cTn. This has led to a proposal of using a lower cutoff for female patients, but it remains controversial.[35–37] The reader is referred to Chapter 13, Acute Coronary Syndrome, for a more detailed discussion of the use of cardiac markers.

CASE 2-4

QUESTION 1: J.R., a 57-year-old male with a history of stable angina, presents to a hospital emergency department. He has sudden-onset chest pressure and tightness, diaphoresis, and nausea that has been waxing and waning for the past few hours. J.R. describes his discomfort as severe at times and not relieved by position change, antacids, or sublingual nitroglycerin. An ECG reveals ST depressions consistent with myocardial ischemia. His cardiac biomarkers reveal CK 220 IU/L, CK-MB 5%, hs-cTnT at 0h is 12 ng/L and at 2h is 16 ng/L. Based on his presentation, ECG, and cardiac biomarkers, J.R. is diagnosed with an MI (non–ST segment-elevation MI) and is admitted for a cardiac catheterization.

Why are the total CK and CK-MB serum concentrations within the reference range despite clear evidence, including elevated hs-cTnT, supporting an acute MI?

Although CK and CK-MB are very helpful laboratory values for identifying and assessing myocardial damage/necrosis, the utility of these values alone can be quite limited. Troponin levels are very sensitive and specific to myocardial cell death, can become positive sooner than do CK and CK-MB, and will remain elevated for a much longer period (up to 10 days). Even if the CK and CK-MB are not elevated, the hs-cTnT can pick up even the smallest amount of myocardial cell death. Based on the clinical picture and the elevated troponin, the patient would be classified as having a non–ST segment-elevation MI.

Myoglobin

Reference Range: Female 12–76 µg/L; Male 19–92 µg/L

Myoglobin, a protein in heart and skeletal muscle cells, provides oxygen to working muscles. Damaged muscle releases myoglobin into the bloodstream. As a cardiac biomarker, myoglobin concentrations in serum rise within 3 hours of insult to the myocardial tissue, peak in about 8 to 12 hours, and return to normal in about a day. Because myoglobin serum concentrations rise more quickly than does CK-MB after myocardial injury, this parameter can be of value in helping rule out MI in the emergency department. Myoglobin serum concentrations, however, tend to be less specific for myocardial tissue compared with CK-MB and troponin; trauma or ischemic injury to noncardiac tissue can also increase serum myoglobin.

Homocysteine

Reference Range: 4–12 µmol/L

Patients with deficiencies in folate, vitamin B_6, or vitamin B_{12} tend to have elevated serum levels of homocysteine. Homocysteine is believed to have a destructive effect on vascular epithelium. With time, patients with elevated homocysteine levels (>12 µmol/L) are believed to be at increased risk for cardiac disease.[38] Screening individuals with a positive family history for elevated homocysteine or those with premature atherosclerosis without typical risk factors has been advocated. Understanding the association between increased homocysteine levels and specific vitamin deficiencies, supplementation of folate, vitamin B_6, and vitamin B_{12} has been used clinically. Although hyperhomocysteinemia may be an independent risk factor for atherosclerosis, to date no studies have shown that lowering homocysteine levels improves cardiovascular outcomes in patients with preexisting atherosclerosis or cardiovascular disease (CVD).[39]

Lactate Dehydrogenase

Reference Range: 100–250 IU/L (adult) or 1.67–4.17 µkat/L

The enzyme lactate dehydrogenase (LDH) is present in the heart, kidney, liver, and skeletal muscle. It is also abundantly present in erythrocytes and lung tissue. Because increased serum concentrations of LDH can be associated with diseases in many different organs and tissues, the diagnostic usefulness of an LDH determination is somewhat limited. There are, however, five isoenzymes of LDH. Although most tissues contain all five isoenzymes, some tissues have a predominance of one of the isoenzymes. LDH_1 and, to a lesser extent, LDH_2 predominate in the heart. Skeletal muscle and the liver have a predominance of LDH_5. LDH_3 and LDH_4 are found in a variety of tissues, including the lungs, RBCs, kidneys, brain, and pancreas. Consequently, identifying specific isoenzymes can increase the diagnostic usefulness of serum LDH determinations.

Brain Natriuretic Peptide

Reference Range: Brain Natriuretic Peptide (BNP) <100 pg/mL or <100 ng/L: >500 pg/mL or >500 ng/L is considered elevated; N-Terminal pro-Brain Natriuretic Peptide (NT-proBNP) <400 pg/mL or <400 ng/L: >2000 pg/mL or >2000 ng/L is considered elevated.

BNP is released from the ventricles because of increased myocardial demand. Elevations in BNP are indicative of patients with CHF and volume overload. To reduce the workload on the heart, BNP counteracts the renin–angiotensin–aldosterone system and causes vasodilatory effects, along with natriuresis (increased excretion of sodium), all geared at reducing blood volume. Patients with some degree of CHF typically have BNP levels >100 ng/L. BNP levels >500 ng/L represent definite CHF, but further evaluation is warranted to more fully characterize the extent of impaired cardiac function.[40] It should be noted that BNP is a substrate of neprilysin and that use of

an angiotensin receptor–neprilysin inhibitor (ARNI) can increase BNP levels.[41] This is not the case for NT-proBNP.[42] NT-proBNP is a by-product from the cleaving of pro-BNP to form BNP; it is also being used in the clinical setting to assess HF. Similar to BNP, there are three generally accepted ranges for NT-proBNP. Patients presenting with an NT-proBNP level <400 ng/L are unlikely to have HF. A level >2000 ng/L is indicative of an HF diagnosis, whereas values 400 to 2000 ng/L are considered uncertain. In both acute and ambulatory HF, there is extensive evidence supporting the use of BNP and NT-proBNP to aid in HF diagnosis; this is especially true in patients presenting with shortness of breath of unknown etiology.[43–57] The reader is referred to Chapter 14, Heart Failure, for a more detailed discussion of the use of BNP and NT-proBNP.

C-Reactive Protein

R***eference Range: 0–1.6 mg/dL or 0–16 mg/L***

C-reactive protein (CRP) is a nonspecific, acute-phase reactant helpful in the diagnosis and monitoring of inflammatory processes (eg, rheumatoid arthritis and bacterial infections). CRP is produced by the liver in response to inflammation. Although an elevation in CRP indicates the presence of an acute inflammatory event, the nonspecific nature of the test does little to identify the cause or location of the inflammation. CRP is similar to an older test, the erythrocyte sedimentation rate (ESR), but it tends to be more sensitive than is ESR and is also associated with a more rapid and greater response to acute inflammation. A potential use of CRP is as a novel risk factor for CVD.[58] CRP has also been used to assess chronic inflammatory diseases such as rheumatoid arthritis and Crohn disease. In addition, because viral infections do not typically increase CRP serum concentrations, the use of CRP as a diagnostic tool to differentiate viral from bacterial infections might be clinically helpful. High-sensitivity CRP is a more sensitive test that has been thought to be a better predictor of CVD risk and statin response, but

its use remains controversial. Routine testing is not part of current guidelines, and stratification and targets have not been validated.[59,60]

LIVER FUNCTION TESTS

Aspartate Aminotransferase

Reference Range: 0–35 IU/L or 0–0.58 µkat/L

The AST enzyme is abundant in heart and liver tissue and moderately present in skeletal muscle, kidney, and pancreas. In cases of acute cellular injury to the heart or liver, the enzyme is released into the blood from the damaged cells. In practice, AST determinations have been used to evaluate myocardial injury and to diagnose and assess the prognosis of liver disease resulting from hepatocellular injury. The serum AST level is increased in >95% of patients after an MI. However, the increase in AST does not occur until 4 to 6 hours after the onset of myocardial injury. Peak AST concentrations are seen in the serum after 24 to 36 hours, returning to the normal range in about 4 to 5 days.

Serum AST values are elevated significantly in patients with acute hepatic necrosis, whether caused by viral hepatitis or a hepatotoxin (eg, carbon tetrachloride). In these situations, the serum concentrations of both AST and alanine aminotransferase (ALT) will be increased, even before the appearance of clinical symptoms (eg, jaundice). The AST and ALT serum concentrations can be increased by as much as 100 times the usual upper limits of normal in the presence of parenchymal liver disease. Patients with intrahepatic cholestasis, posthepatic jaundice, or cirrhosis usually experience more moderate elevations of AST, depending on the extent of cell necrosis. The AST serum concentration is usually higher than that of ALT in patients with cirrhosis, and the AST increase is usually about four to five times greater than is the upper limit of normal.

Alanine Aminotransferase

Reference Range: 0–35 IU/L or 0–0.58 µkat/L

The ALT enzyme is found in essentially the same tissues that have high concentrations of AST, but ALT is generally considered to be more specific to the liver, because ALT concentrations in nonhepatic tissues are low.[61] Elevations in serum ALT are more specific for liver-related injuries or diseases. Although ALT is relatively more abundant in hepatic tissue versus cardiac tissue than is AST, the liver still contains 3.5 times more AST than ALT. Serum concentrations of both AST and ALT increase when disease processes affect liver cell structure. Evaluating the ratio of ALT to AST can be potentially useful, particularly in the diagnosis of viral hepatitis. The ALT/AST ratio frequently exceeds 1.0 with alcoholic cirrhosis, chronic liver disease, or hepatic cancer. However, ratios <1.0 tend to be observed with viral hepatitis or acute hepatitis, which can be useful when diagnosing liver disease.[62]

Alkaline Phosphatase

Reference Range: 20–130 IU/L or 0.33–2.17 µkat/L

The alkaline phosphatases (ALPs) constitute a large group of isoenzymes that play important roles in the transport of sugar and phosphate. These isoenzymes of ALP have different physiochemical properties and originate from different tissues (eg, liver, bone, placenta, and intestine). In normal adults, ALP is derived primarily from liver and bone and found in smaller quantities in the intestines, kidneys, and white blood cells (WBCs).[61] Although only small amounts of ALP are present in the liver, this enzyme is secreted into the bile, and substantially elevated ALP serum concentrations can be seen with mild intrahepatic or extrahepatic biliary obstruction. Thus, the presence of early bile duct abnormalities can result in elevated ALP before increases in the serum bilirubin are observed. Drug-induced cholestatic jaundice (eg, chlorpromazine or sulfonamides) can increase serum ALP concentrations. In mild cases of acute liver cell damage, ALP levels are seldom elevated.

Even in cirrhosis, ALP concentrations are variable and depend on the degree of hepatic decompensation and obstruction.

The osteoblasts in bone produce large amounts of ALP, and marked serum elevations can be seen in Paget disease of the bone, hyperparathyroidism, osteogenic sarcoma, osteoblastic cancer metastatic to bone, and other conditions of pronounced osteoblastic activity. The serum ALP is increased during periods of rapid bone growth (eg, infancy, early childhood, and healing bone fractures) and during pregnancy because of the contributions of the placenta and fetal bones.

Gamma-Glutamyl Transferase

Reference Range: Male, 9–50 IU/L; Female, 8–40 IU/L

Although the enzyme γ-glutamyl transferase (GGT) is found in the kidney, liver, intestine, prostate, and pancreas, its major clinical value is in the evaluation of hepatobiliary disease. An increase in the serum concentration of GGT parallels the increase of ALP in obstructive jaundice and infiltrative disease of the liver. However, increased ALP in the presence of a normal GGT is more suggestive of muscular or bone-related issues, because GGT is not found in bone. GGT is one of the more sensitive liver enzymes for identifying biliary obstruction and cholecystitis. GGT can also be elevated in patients with obesity.[61] Because GGT is a hepatic microsomal enzyme, tissue concentrations increase in response to microsomal enzyme induction by alcohol and other drugs (eg, carbamazepine, phenobarbital, and phenytoin). As a result, GGT is a sensitive indicator of recent or chronic alcohol exposure.

Bilirubin

Total Bilirubin—Reference Range: 0.1–1.0 mg/dL or 2–18 µmol/L
Direct (Conjugated) Bilirubin—Reference Range: 0–0.2 mg/dL or 0–4 µmol/L

Bilirubin is primarily a breakdown product of Hgb and is formed in the reticuloendothelial system (**Fig. 2-1**, step 1). It is then transferred into the blood (step 2), where it is almost completely bound to serum albumin (step 3). When bilirubin arrives at the sinusoidal surface of the liver cells, the free fraction is rapidly taken up into the cell (step 4) and converted primarily to bilirubin diglucuronide (step 5). A monoglucuronide that is metabolized predominantly to the diglucuronide is also formed. The conjugated bilirubin diglucuronide is then excreted into the bile (step 6) and appears in the intestine, where bacteria convert most of it to urobilinogen (step 7). The majority of urobilinogen is destroyed or excreted in the feces (step 13), but a small portion is reabsorbed into the blood (step 8) and either reabsorbed into the liver (step 9) and subsequently excreted into the bile (step 12) or excreted into the urine (step 10). Urobilinogen is responsible for the straw color of the urine and the yellowish-brown color of the feces. The mechanism by which conjugated bilirubin in the liver cell is transferred to the blood (step 14) is not well understood. However, in many types of liver disease, conjugated (direct) bilirubin is present in increased concentrations in the blood. When this concentration exceeds 0.2 to 0.4 mg/dL, bilirubin will begin to appear in the urine (step 11). Unconjugated (indirect) bilirubin is water insoluble and is highly bound to serum albumin; both factors account for its lack of excretion in the urine.[63]

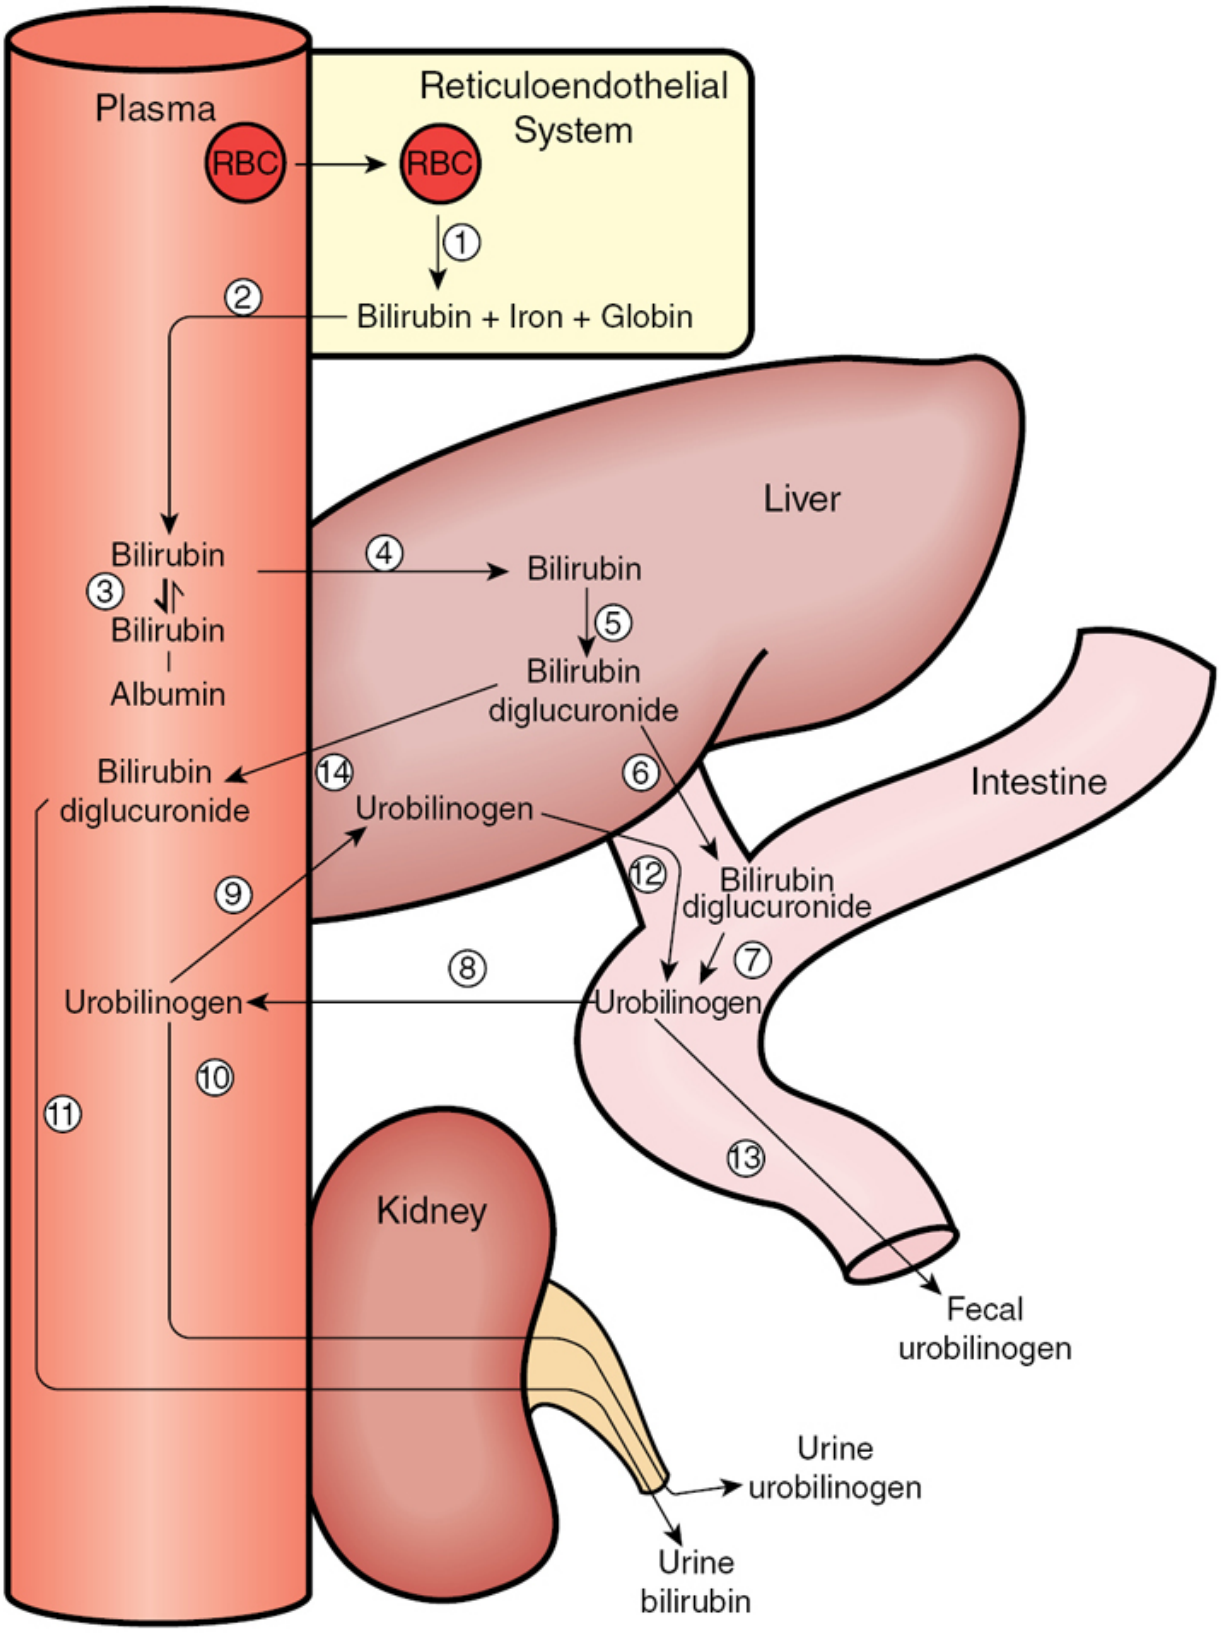


Figure 2-1 Bilirubin metabolism.

When bilirubin is reported by the lab, it is usually reported as total bilirubin, which consists of both conjugated and unconjugated fractions. If there is an elevation in any of the fractions, it will lead to an elevation of total bilirubin concentrations. It is important to note that with the exception of neonates, the majority of bilirubin should consist of the conjugated fraction.[61]

MISCELLANEOUS TESTS

Amylase and Lipase

Amylase (reference range: 35–118 IU/L or 0.58–1.97 μkat/L) and lipase (reference range: 10–160 IU/L or 0–2.67 μkat/L) are enzymes produced by the pancreas and secreted into the duodenum to assist in the digestive process. Small amounts of both enzymes are also found in the saliva and stomach. Significantly elevated levels of either enzyme are suggestive of pancreatic damage.

Amylase is responsible for breaking down complex carbohydrates into simple sugars. Significant elevations in serum amylase are observed in patients with acute pancreatitis or pancreatic duct obstruction. Amylase levels tend to rise 6 to 48 hours after onset of the disease and usually return to normal 3 days after the acute event. In chronic pancreatitis or obstruction, amylase levels may remain elevated for longer periods. Other nonpancreatic conditions (eg, bowel perforation, biliary disease, perforated peptic ulcer, ectopic pregnancy, and mumps) can be associated with elevated serum amylase levels.

Lipase is responsible for breaking down triglycerides (TGs) into fatty acids. Elevated serum lipase levels are also suggestive of pancreatic disease and tend to be more specific for pancreatic disease than for amylase. Nonpancreatic conditions such as gallbladder disease or biliary cirrhosis can also lead to elevated lipase levels. The onset of lipase elevation is similar to that of amylase; however, lipase typically remains elevated for 5 to 7 days,

and can be useful in diagnosing patients in later stages of pancreatic disease. Narcotics (eg, morphine) can constrict the sphincter of Oddi and increase serum concentrations of both amylase and lipase.

Prostate-Specific Antigen

Reference Range: 0–4 ng/mL or 0–4 µg/L

Prostate-specific antigen (PSA) is a protease glycoprotein produced almost exclusively by prostate epithelial cells. Large quantities of PSA are carried in semen; only low levels are found in the blood. Serum concentrations of PSA are increased when the normal prostate glandular structure is disrupted by benign or malignant tumor or inflammation (prostatitis). More than half of males with benign prostatic hyperplasia (BPH) have elevated serum PSA concentrations. PSA is also a valuable parameter for staging and monitoring the progression and response to therapy of prostate cancer.[64]

The prostate gland increases in size with age; therefore, it is expected that older males will have higher PSA levels compared with younger males. PSA serum concentrations can also increase after prostatic manipulation such as digital rectal examination (DRE), catheter placement, transrectal ultrasound, cystoscopy, or biopsy of the prostate. In addition, serum PSA will increase 24 to 48 hours after ejaculation. Although elevated serum concentrations of PSA can occur in males with BPH, concentrations tend to be higher and encountered more often in males with cancer. Males with PSA levels between 4 and 10 ng/mL should be evaluated further for potential prostate cancer.

The serum half-life of PSA is 2 to 3 days, but serum PSA concentrations can remain high for several weeks after manipulation of the prostate. Circulating serum PSA is bound to plasma proteins, and the capability exists to measure both total and free (unbound) PSA concentrations. Increased risk of prostate cancer has been observed in males with a free PSA to total PSA ratio of <0.25.[65] An

aggressive approach to localize prostate cancer for males with life expectancies >10 years is now favored.[64,66]

Thyroid-Stimulating Hormone

Reference Range: 0.5–4.7 µIU/mL or mIU/L

Thyroid-stimulating hormone (TSH, also known as thyrotropin) is secreted by the pituitary gland to stimulate the thyroid gland to produce the thyroid hormones T_4 and T_3. TSH is measured, often in conjunction with the thyroid hormones, to diagnose thyroid disorders and to monitor exogenous thyroid supplementation therapy. The reader is referred to Chapter 52, Thyroid Disorders, because it provides a more detailed discussion of the clinical implications of altered thyroid laboratory findings.

Procalcitonin

Procalcitonin is a precursor of calcitonin and is typically undetectable in healthy individuals. Elevations in procalcitonin occur in patients with inflammation secondary to bacterial infections; however, a similar increase is not observed in patients with inflammation secondary to viral infections or noninfectious conditions. Once there is a systemic inflammation due to bacterial infection, synthesis of procalcitonin will be induced in almost all tissues and then released into the blood.[67] Interestingly, increases in calcitonin are not seen in patients with elevated procalcitonin. In patients with sepsis or sepsis syndrome, procalcitonin levels <0.5 ng/mL have been associated with a low risk of progression to severe sepsis, and levels >2.0 ng/mL represent a high risk for severe sepsis. Trials involving lower respiratory tract infections have suggested that antibiotic therapy should be discouraged in patients with procalcitonin levels <0.25 ng/mL but encouraged for those with levels ≥0.5 ng/mL. These criteria have also been used as a guide for discontinuing therapy as infections resolve; however, there are differences in how procalcitonin levels are managed among different institutions.

Additional further trials will help accurately define the role of procalcitonin testing.

Cholesterol and Triglycerides

A detailed discussion of hypercholesterolemia and lipid disorders is provided in Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease. For convenience, the current range of desired values for total cholesterol (TC), low-density lipoproteins (LDLs), high-density lipoproteins (HDLs), and fasting TGs has been incorporated in **Table 2-2**.

HEMATOLOGY

There are several different hematologic cell types that originate from the hematopoietic stem cell. Each cell line has a defined role and unique contribution to the overall homeostatic process and may be found in the bone marrow, lymph system, or blood. Typically, routine clinical laboratory testing involves measuring concentrations of mature myeloid cells found in the blood. **Figure 2-2** illustrates the various lineages derived from the hematopoietic stem cell.[68] The cells derived from the myeloid linage are the focus of the following discussion. Readers are encouraged to refer to Section 16, Hematology and Oncology, to gain further understanding of the clinical relevance of lymphoid and myeloid cells (Fig. 2-2).

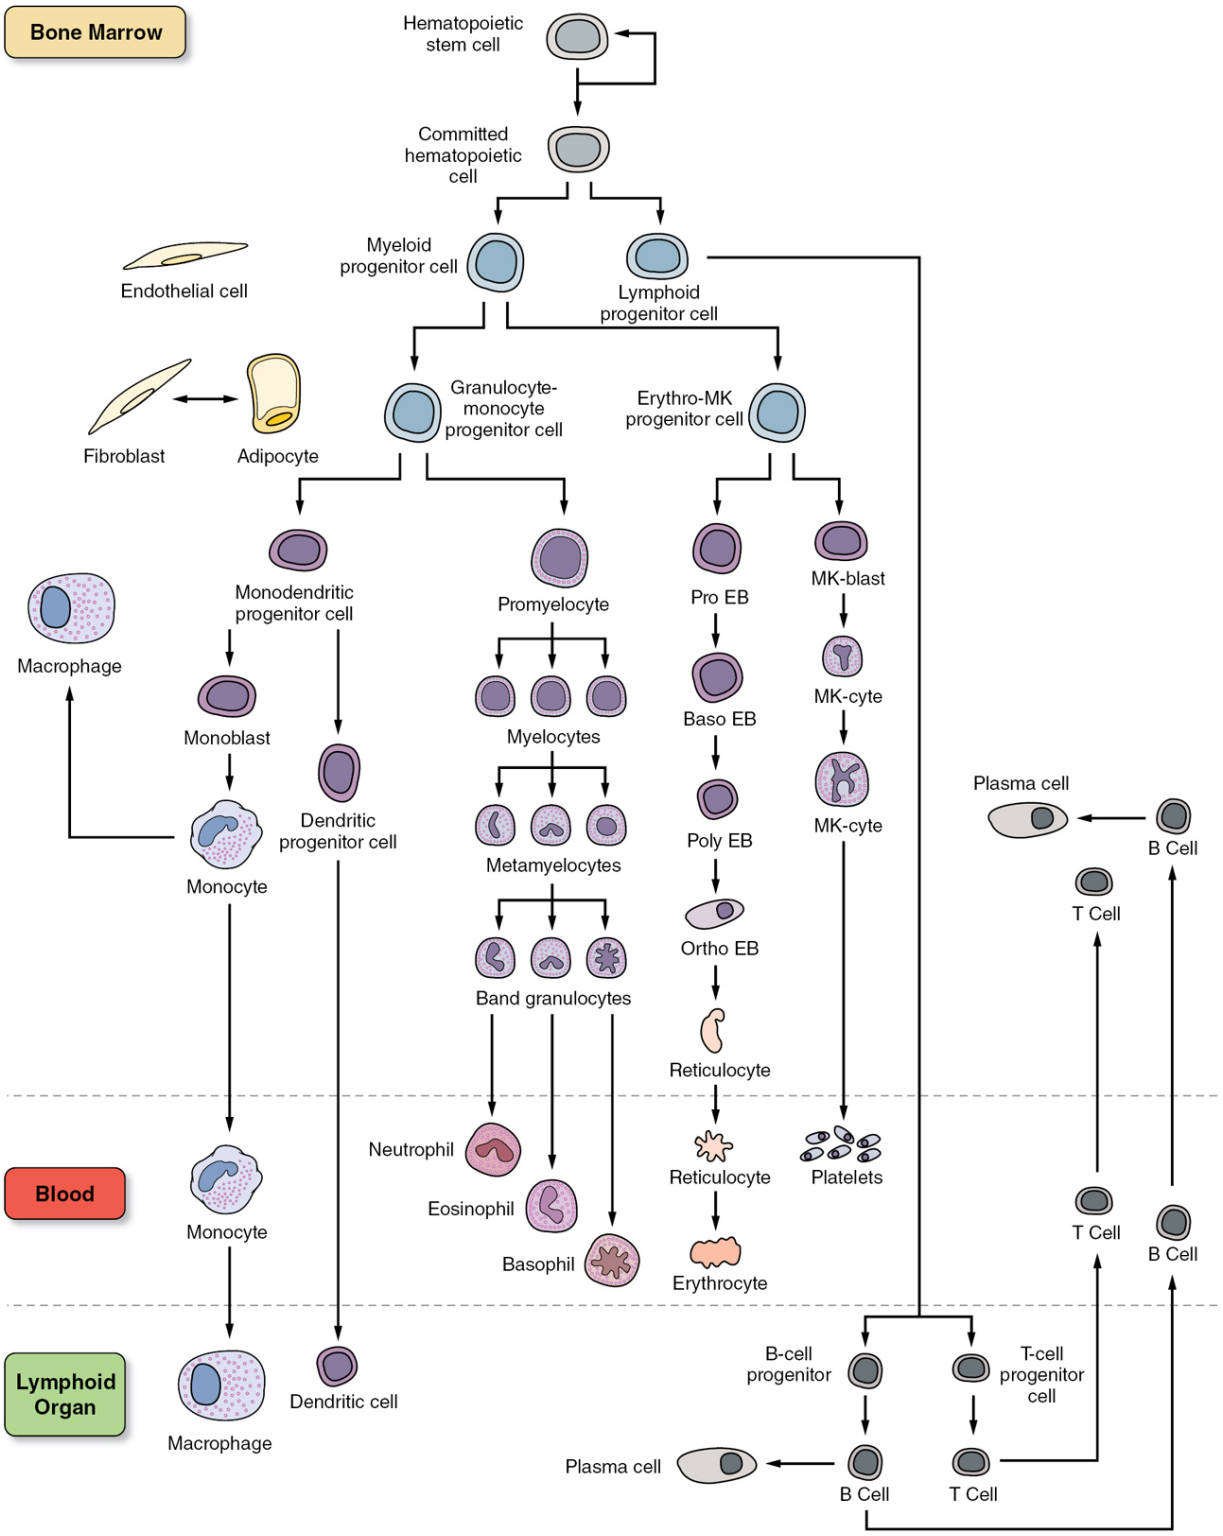

Figure 2-2 Hematopoietic stem cell lineage. MK, megakaryocyte; EB, erythroblast. (Adapted with permission from Greer JP, Foerster

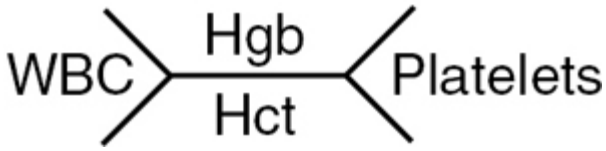
J, Rodgers GM, et al, eds. *Wintrobe's Clinical Hematology*. 12th ed. Lippincott Williams & Wilkins; 2009:80.)

Complete Blood Count

The complete blood count (CBC) is one of the most commonly ordered clinical laboratory tests. A CBC measures the RBCs, Hgb, hematocrit (Hct), platelets, mean cell volume (MCV), mean cell hemoglobin concentration (MCHC), mean platelet volume (MPV), and total WBCs. CBC with differential will measure all the values mentioned earlier; in addition, it will also measure the number of each type of WBCs. An abbreviated method of noting hematologic parameters in clinical practice is noted in the following figure.



Red Blood Cells (Erythrocytes)

Reference Range: Males, 4.3–5.9 × 10^6/μL or 4.3–5.9 × 10^{12}/L
Reference Range: Females, 3.5–5 × 10^6/μL or 3.5–5 × 10^{12}/L
Erythrocytes or RBCs are produced in the bone marrow, released into the peripheral blood, circulated for ~120 days, and cleared by the reticuloendothelial system. The primary function of RBCs is to transport oxygen linked to Hgb from the lungs to tissues. The concentration of RBCs in the blood can be measured to detect anemia, calculate RBC indices, or calculate the Hct. Hct and Hgb concentrations are generally used to monitor quantitative changes in RBCs.

Hematocrit

Reference Range: Males, 40.7%–50.3% or 0.4–0.503
Reference Range: Females, 36%–44.6% or 0.36–0.446

Hct (packed cell volume) is the percentage of RBCs to the total blood volume and is determined by centrifuging a capillary tube of whole blood and comparing the height of the settled RBCs to the height of the column of whole blood. A decrease in Hct may result from bleeding, the bone marrow suppressant effects of drugs, chronic diseases, genetic alterations in RBC morphology, or hemolysis. An increase in Hct may result from hemoconcentration, polycythemia vera, or polycythemia secondary to chronic hypoxia.

Hemoglobin

Reference Range: Males, 13.8–17.5 g/dL or 138–175 g/L
Reference Range: Females, 12.1–15.3 g/dL or 121–153 g/L
Hgb is the major oxygen-carrying compound contained in RBCs. Therefore, total Hgb concentration primarily depends on the number of RBCs in the blood sample. As mentioned with Hct, medical conditions that impact the number of RBCs will also affect Hgb concentration. As discussed previously, glycated Hgb (A_{1c}) is a related test used to monitor diabetes mellitus.

Red Blood Cell Indices

RBC indices (also known as Wintrobe indices) are useful in the classification of anemias. These indices include the MCV, the mean cell hemoglobin (MCH), and the MCHC. These indices are calculated in Eqs. 2-9 to 2-11:

$$\text{MCV} = \text{HCT}\,(\%) \times 10/\text{RBC}\,(\text{in millions}/\mu\text{L}) = 80 - 97.6\,(\text{in } \mu\text{m}^3 \text{ or Fl}) \quad \textbf{(Eq. 2-9)}$$

$$\text{MCH} = \text{Hgb}\,(\text{in g/dL}) \times 10/\text{RBC}\,(\text{in millions}/\mu\text{L}) = 27 - 33\,(\text{in pg}) \quad \textbf{(Eq. 2-10)}$$

$$\text{MCHC} = \text{Hgb (in g/dL)} \times 100/\text{Hct (\%)} = \quad \textbf{(Eq. 2-11)}$$
$$33 - 36 \text{ (in g/dL)}$$

MEAN CELL VOLUME

The MCV detects changes in cell size. A decreased MCV indicates a microcytic cell, which can result from iron deficiency anemia or anemia of chronic inflammation. A large MCV indicates a macrocytic cell, which can be caused by a vitamin B_{12} or folic acid deficiency. Underlying disease states (eg, habitual alcohol ingestion, chronic liver disease, anorexia nervosa, hypothyroidism, reticulocytosis, and hematologic disorders) may also present with an elevated MCV secondary to deficiencies in these vitamins.[69] The MCV can be normal in a patient with a "mixed" (microcytic and macrocytic) anemia. Note that a direct assessment of a blood smear by a microscopic examination is the gold standard for confirming RBC size.

MEAN CELL HEMOGLOBIN

The MCHC is a more reliable index of RBC Hgb than is MCH. MCH measures the weight of Hgb in the RBCs in a sample, and MCHC measures the concentration of the RBCs contained within a sample. In normochromic anemias, changes in the size of RBCs (MCV) are associated with corresponding changes in the weight of Hgb (MCH), but the concentration of Hgb (MCHC) remains normal. Changes in the Hgb content of RBCs alter the color of these cells. Thus, hypochromic refers to a decrease in RBC Hgb, reflected by reduced MCHC, and may indicate iron deficiency anemia. Conversely, hyperchromic RBCs have an elevated MCHC because of the presence of greater amounts of Hgb. Hyperchromic cells are not commonly encountered.

Reticulocytes

Reference Range: Adults, 0.5%–1.5% of RBCs or 0.005–0.015

Reticulocytes are young, immature erythrocytes, and typically comprise about 1% of the RBCs. The reticulocyte count measures the percentage of these new cells in the circulating blood. An increase in the number of reticulocytes implies that an increased number of erythrocytes are being released into the blood in response to a stimulus. Reticulocyte count is a good indicator of bone marrow activity because it represents a recent production. Because erythrocytes regenerate rapidly, reticulocytosis can be noted within 3 to 5 days of hemolysis or after a hemorrhagic episode. Appropriate treatment of anemias caused by iron, vitamin B_{12}, or folic acid deficiencies should result in an increased reticulocyte count. Caution must be exercised in the interpretation of reticulocyte counts. Changes in the number of RBCs will result in proportional changes in the reticulocyte count because the latter is reported as a percentage of the number of RBCs.

Erythrocyte Sedimentation Rate

Reference Range: 0–30 mm/hour

The ESR is the rate (expressed in mm/hour) at which erythrocytes settle to the bottom of a test tube through the forces of gravity and in response to fibrinogen levels in the blood. The ESR is a nonspecific value and may be increased abnormally in acute and chronic inflammatory processes, acute and chronic infections, neoplasms, infarction, tissue necrosis, rheumatoid-collagen disease, dysproteinemias, nephritis, and pregnancy. However, ESR can also be affected by changes not related to the inflammation (eg, change in erythrocyte size, shape, or number). Laboratory technique can also affect the sedimentation rate substantially. Because many factors can enhance the settling rate of RBCs, moderate to marked elevation of the ESR merely indicates an inflammatory component to a disease state. An increased ESR in the setting of a normal physical examination is usually transient and is rarely the harbinger of serious occult disease.[70]

White Blood Cells

Reference Range: 3.8–9.8 × 10^3/μL or 3.8–9.8 × 10^9/L

Leukocytes or WBCs comprise five different types of cells. Neutrophils are the most abundant of the circulating WBCs, followed in order of frequency by lymphocytes, monocytes, eosinophils, and basophils. The neutrophils, eosinophils, basophils, and monocytes are formed from stem cells in the bone marrow. Lymphocytes are formed primarily in the lymph nodes, thymus, spleen, and, to a lesser extent, in the bone marrow (Fig. 2-2). Each WBC type has a unique function, and it is best to consider them independently rather than collectively as "leukocytes."[71] Ultimately, all WBCs contribute to host defense mechanisms.

NEUTROPHILS

Reference Range: 40%–70% of WBCs

The terms *polys, segs, polymorphonuclear neutrophils,* and *granulocytes* are synonymous with the term *neutrophil* in clinical practice. The number of neutrophils is commonly increased during bacterial or fungal infections because these cells are essential in killing invading microorganisms. Although the bone marrow increases the production of new leukocytes, there is also an increase in the number of circulating immature neutrophils (eg, bands); this phenomenon is commonly referred to as a *left shift*, which suggests acute bacterial infection.

However, neutrophils are also important in the pathogenesis of tissue damage in some noninfectious diseases, such as rheumatoid arthritis, inflammatory bowel disease, asthma, MI, or gout.[72] Increased neutrophils or neutrophilia can also be encountered during metabolic toxic states (eg, diabetic ketoacidosis, uremia, and eclampsia) and during physiologic response to stress (eg, physical exercise and childbirth). Drugs (eg, epinephrine and corticosteroids) can also cause significant neutrophilia, primarily caused by demargination from blood vessel walls.

Agranulocytosis and absolute neutrophil count

The condition involving decreased neutrophils, or *neutropenia*, is defined as a neutrophil count of <2000 cells/μL; *agranulocytosis* refers to severe neutropenia. The most common causes of neutropenia are metastatic carcinoma, lymphoma, and chemotherapeutic agents. The degree of neutropenia is often expressed by the absolute neutrophil count (ANC). The ANC is defined as the total number of granulocytes (polymorphonuclear leukocytes and band forms) present in the circulating pool of WBCs and can be calculated as WBC × (% neutrophils + % bands)/100. Generally, the risk of infection is low when the ANC exceeds 1000/μL; however, the risk of infection increases significantly when the ANC is <500/μL. The risk of developing bacteremia is increased further as the ANC decreases to <100/μL, a condition commonly referred to as *profound neutropenia*. The most common causes of neutropenia are metastatic carcinoma, lymphoma, and chemotherapeutic agents. The reader is referred to Chapter 75, Prevention and Treatment of Infections in Neutropenic Cancer Patients, for a more detailed explanation.

LYMPHOCYTES

Reference Range: 22%–44% of WBCs

Lymphocytes constitute the second most common WBC in circulating blood. These leukocytes respond to foreign antigens by initiating the immune defense system. The vast majority of lymphocytes are located in the spleen, lymph nodes, and other organized lymphatic tissue. The lymphocytes circulating in blood represent <5% of the total amount in the body.

There are two major types of lymphocytes. T lymphocytes (thymic dependent) participate in cell-mediated immune responses, and B lymphocytes (bone marrow derived) are responsible for humoral antibody responses. Therefore, diseases affecting lymphocytes primarily manifest themselves as immune deficiency disorders that render the patient unable to defend against normal pathogens (see Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus

Infection) or as autoimmune diseases in which immune responses are directed against the body's own cells.[71]

Increased numbers of lymphocytes on a white count differential sometimes accompany lymphoma (see Chapter 96, Adult Hematologic Malignancies) and viral infections. A relative lymphocytosis is sometimes encountered when the total lymphocytes have remained constant despite a decline in the total neutrophils.

MONOCYTES

Reference Range: 4%–11% of WBCs

Monocytes are formed in the bone marrow and are the precursors to macrophages and antigen-presenting cells (dendritic cells), which are found in the body's tissues.[73] Macrophages and dendritic cells are phagocytic cells that engulf foreign antigens or dead or dying cells. Dendritic cells also present fragments of antigens to T and B lymphocytes. Monocytosis may be observed in mononucleosis, subacute bacterial endocarditis, malaria, and tuberculosis, as well as during the recovery phase of some infections.

EOSINOPHILS

Reference Range: 0%–8% of WBCs

Because eosinophils have surface receptors that bind IgG and IgE, they can modify reactions associated with IgG- and IgE-mediated degranulation of mast cells. Primary lysosomal granules, small dense granules, and specific or secondary granules are the three types of granules found within eosinophils. The latter granules account for most of the biologic activity of eosinophils and are toxic to parasites, tumor cells, and some epithelial cells.[74]

Eosinophils have phagocytic activity, catalyze the oxidation of many substances, facilitate killing of microorganisms, initiate mast cell secretion, protect against various parasites, and play some role in host defense. Eosinophilia is probably most commonly associated with allergic reactions to drugs, allergic disorders (eg, hay fever, asthma, and eczema), invasive parasitic infections (eg, hookworm,

schistosomiasis, and trichinosis), collagen vascular diseases (eg, rheumatoid arthritis, eosinophilic fasciitis, and eosinophilia–myalgia syndrome), and malignancies (eg, Hodgkin lymphoma).[74–77]

BASOPHILS

Reference Range: 0%–3% of WBCs

During infection or inflammation, basophils leave the blood and mobilize as mast cells to the affected site and release granules. These granules contain histamine, serotonin, prostaglandins, and leukotrienes. Degranulation results in an increased blood flow to the site and may compound inflammatory processes. An increase in basophils commonly accompanies allergic and anaphylactic responses, chronic myeloid leukemia, myelofibrosis, and polycythemia vera. A decrease in the number of basophils is generally not readily apparent because of the small number of these cells in the blood.[71]

CASE 2-5

QUESTION 1: K.T., a 50-year-old female, is hospitalized with a sustained high fever of 102.56 °F (39.2 °C) and severe back pain. The results of the CBC and leukocyte differential are as follows:

Total WBC count: 21,000/μL
Neutrophils: 74%
Bands: 6%
Lymphocytes: 14.6%
Monocytes: 8%
Eosinophils: 1%
Basophils: 0%

Imaging and other blood work were ordered. K.T. is diagnosed with an abscess in her lower back and *Staphylococcus aureus* bacteremia.

How is K.T.'s laboratory report consistent with a systemic bacterial infection?

WBCs are the host's chief defense system, and the neutrophil is the main component of that system. During bacterial infections, the leukocyte count and the neutrophils are generally increased, and a left shift (increase in bands) may be noticeable. The percentage of

other types of WBCs is decreased proportionately because the number of neutrophils is increased.

As the infection progresses, the percentage of band cells may decrease as a result of an increase in the number of neutrophils that have a longer half-life. This decrease in bands does not necessarily indicate improvement. A decrease in the percentage of neutrophils with a decrease in the total WBC count is characteristic of effective antibiotic therapy.

CASE 2-5, QUESTION 2: The *S. aureus* causing K.T.'s bacteremia is found to be methicillin sensitive, and she is started on oxacillin 2 million units IV every 4 hours for treatment. After about a week of therapy, K.T. develops a fine red rash all over her body, mild lymphadenopathy, low-grade fever, and generalized swelling. The CBC shows a total WBC count of 8600/μL with 11% eosinophils. What is the significance of this eosinophil count?

In the clinical setting, absolute leukocyte counts may be used in conjunction with normal reference values. Absolute counts are calculated by multiplying the percentage of each individual cell by the total leukocyte count. Eosinophils are usually increased in allergic reactions; therefore, a drug-induced hypersensitivity reaction is a strong probability in K.T., with an absolute count of 946 eosinophils/μL (ie, 11% of 8600 leukocytes). The clinician should be suspicious of an allergic drug reaction when absolute eosinophil counts exceed 300 cells/μL. Eosinophils may increase before, after, or concurrent with other evidence of allergy (eg, rash). Eosinophilia without evidence of allergy is not sufficient cause to discontinue a suspected medication unless the eosinophilia is significant (ie, >2000 cells/μL). In addition, the absence of eosinophilia certainly does not rule out an allergic diagnosis in a patient exhibiting clear clinical manifestations of an apparent allergic reaction.

Thrombocytes

Reference Range: 150–450 × 10^3/μL or 150–450 × 10^9/L

Thrombocytes, commonly referred to as platelets, are tiny fragments of cells that assist with normal blood clotting. Platelet testing is included as part of a CBC and is often ordered along with other coagulation studies to evaluate bleeding and/or clotting disorders. Decreased platelet counts or thrombocytopenia may lead to petechiae, ecchymosis, and spontaneous hemorrhage.

Causes include decreased platelet production, accelerated destruction, loss from excessive bleeding or trauma, dilution of blood samples secondary to blood transfusion, sequestration secondary to hypersplenism, disseminated intravascular coagulation, infection, or systemic lupus erythematosus. Malignancy, rheumatoid arthritis, iron deficiency anemia, polycythemia vera, and post splenectomy syndromes are the most common causes of elevated platelet counts or thrombocytosis.

Coagulation Studies

The control of bleeding depends on the formation of a platelet plug and the formation of a stable fibrin clot. The formation of this clot depends on the complex interactions of plasma proteins and clotting factors. The prothrombin time (PT), international normalized ratio (INR), and activated partial thromboplastin time (aPTT) are used to diagnose coagulation abnormalities or to monitor the effectiveness of patients receiving anticoagulation therapy. When used to assess drug therapy, achieving a value outside the reference range is in fact a therapeutically desirable outcome.

ACTIVATED PARTIAL THROMBOPLASTIN TIME

Reference Range: 22–37 seconds

aPTT measures the time it takes the body to form a clot. aPTT depends on the activity of factors VIII, IX, XI, and XII (intrinsic pathway) and the factors involved in the final common pathway of the clotting cascade (II, X, and V). aPTT is commonly measured to detect bleeding disorders and coagulation deficiencies and monitor unfractionated heparin therapy. The reader is referred to Chapter 11,

Thrombosis, for more detailed information regarding the use of coagulation parameters in treating and monitoring thrombotic disorders.

PROTHROMBIN TIME

Reference Range: 10–13 seconds

Prothrombin is synthesized in the liver, and is converted to thrombin during the blood clotting process. Thrombin formation is the critical event in the hemostatic process because thrombin creates fibrin monomers that ultimately assemble into a clot and stimulates platelet activation. The PT test evaluates the integrity of the extrinsic and common pathways and directly measures the activity of clotting factors V, VII, and X, prothrombin (factor II), and fibrinogen (factor I). Automated laboratory instruments measure PT by recording the time required for the blood to clot after a reagent (ie, tissue thromboplastin) has been added to the patient's blood sample. It is recorded in seconds and is compared to a normal range that reflects PT values in healthy individuals. An abnormal PT is often caused by liver injury and/or by treatment with systemic blood thinners.

INTERNATIONAL NORMALIZED RATIO

Because different labs use different reagents, the PT results obtained from one reagent cannot be reliably compared with another reagent. Therefore, the INR is used as a standard unit to report the result of a PT test. The INR is the recommended method to monitor both the initiation and maintenance of anticoagulant therapy, most notably warfarin. Individuals who have normal blood clotting and are not on anticoagulation therapy should have an INR of 1. For patients on anticoagulation therapy, the target INR (ie, therapeutic range) is usually between 2.0 and 4.0 depending on the clinical indication and other patient-specific factors. Outside of the therapeutic range, the higher the INR, the higher the likelihood of bleeding because the blood is taking longer to clot. Conversely, if the INR is lower, there is an increased risk of developing a clot. Many factors including medications (eg, metronidazole, trimethoprim–sulfamethoxazole,

amiodarone, and azole antifungals), vitamin K intake, alcohol use, and certain medical conditions (eg, HF, cancer, and thyroid disorders) can influence the INR.

The INR is calculated using Eq. 2-12, where the prothrombin ratio (PTR) is the ratio between the patient's PT and the laboratory's control PT, and the ISI is the international sensitivity index. Commercial manufacturers quantify the ISI for the specific thromboplastin reagent used in each lot and report this information in the product package insert:

$$\mathrm{INR} = \{\mathrm{PT\ (patient)} / \mathrm{PT(control)}\}^{\mathrm{ISI}} = \mathrm{PTR}^{\mathrm{ISI}} \qquad \textbf{(Eq. 2-12)}$$

URINALYSIS

A standard urinalysis includes physical, chemical, and microscopic evaluations to assist with diagnosis of various urologic conditions. It begins with a simple observation of the color and the gross general appearance of the urine specimen. The urine pH and specific gravity are then recorded. Formed elements in the urine are examined microscopically, and the urine is searched routinely for pathologically significant substances that are normally not present (eg, glucose, blood, ketones, and bile pigments). Urine specimens should be evaluated quickly after collection to minimize unreliable results. The reader is referred to Chapter 71, Urinary Tract Infections, for a more detailed description of the use of urinalysis in the detection and monitoring of urinary tract infections (UTIs).

Gross Appearance of the Specimen

The concentrated, first-morning urine specimen is usually analyzed to eliminate effects of undue dilution as a result of water intake. The color should be slightly yellow, depending on the degree of dilution, and the appearance should be clear. The appearance of the urine may reveal clouds of crystals, bilirubin, blood, porphyrins, proteins,

food or drug colorings, or melanin. Discolored urine is abnormal. A red coloration of the urine may be imparted by blood, porphyria, or ingestion of phenolphthalein. A brown urine color may be caused by the acid hematin of blood or from melanin pigments. Medications such as nitrofurantoin and/or metronidazole can also contribute to this color change. Excessive excretion of urobilinogen or the effects of drugs such as rifampin or phenazopyridine may cause a dark orange urine color. A blue to blue-green color of the urine may result from the systemic administration of methylene blue.

Specimen pH

When freshly produced, urinary pH can range from 4.5 to 8 but is mostly acidic because of metabolic activity. Alkaline urine may indicate an aged specimen, systemic alkalosis, failure of renal acidifying mechanisms, or infection in the urinary tract.

Specific Gravity

Urinary specific gravity provides information regarding a patient's hydration status. A normal morning urine specimen should have a specific gravity of 1.003 to 1.030. The upper end of this range is close to the maximal concentrating ability of the kidney. A value of ≤1.010 supports relative hydration, whereas a value >1.020 indicates relative dehydration.

Protein

Proteinuria is a classic sign of renal injury. If proteinuria is found during the evaluation of a patient with a nonrenal illness, it suggests that the disease may also involve the kidneys (ie, hypertension and diabetes).[78] A healthy adult generally excretes 30 to 130 mg/day of protein into the urine.

Protein in a urine sample is generally tested qualitatively on a random urine sample by a dipstick method and is usually reported on

a scale of 0 (<30 mg/dL), 1+ (30–100 mg/dL), 2+ (100–300 mg/dL), 3+ (300–1000 mg/dL), and 4+ (>1000 mg/dL). A positive qualitative test result for urine protein should be repeated after a few days because transient proteinuria can accompany various physiologic and pathologic states, even when kidney function is normal. Therefore, patients with HF, seizures, or febrile illnesses and normal renal function need not undergo invasive renal function tests if the proteinuria is modest and likely to be transient. Another qualitative evaluation of proteinuria can be performed in about 2 weeks to confirm the diagnosis of transient proteinuria.[79] If subsequent qualitative test results are positive, a 24-hour urine sample should be collected to quantitatively test for protein and creatinine (see the section on Creatinine Clearance). In patients with a normal 24-hour urinary protein concentration, previous positive qualitative test results probably represent either false-positive results or a transient phenomenon.[78] A laboratory parameter being used with increased frequency to assess proteinuria is the urine albumin to urine creatinine ratio (UACR). This measurement tends to be less influenced by fluctuations in urine concentration and may offer a more reliable indication of proteinuria. The reference range for UACR is <30 mg/g.

MICROSCOPIC EXAMINATION

The urine sediment is examined for RBCs, WBCs, casts, yeast, crystals, and epithelial cells.

RBCs should be absent in normal urine, although <4 to 6 RBCs per high-power field (HPF) would still be considered in the normal range. Bleeding or clotting disorders, some collagen diseases, and various bladder, urethral, and prostatic conditions may cause microscopic hematuria. In females, vaginal blood occasionally contaminates the urine specimen, but the presence of numerous squamous epithelial cells should be sufficient to alert clinicians to this artifact.

WBCs should be virtually absent in normal urine, although up to 5 WBCs/HPF would still be within the reference range. Similarly,

leukocyte esterase, an enzyme found in most WBCs, is absent in normal urine. The presence of elevated WBCs in the urine (pyuria) and/or leukocyte esterase suggests an acute infection in the urinary tract. Some noninfectious inflammatory diseases of the kidney, ureter, or bladder may also contribute WBCs to the urine sediment.

Normal urine also contains chemicals called nitrates. When certain bacteria like *Escherichia coli* enter the urinary tract, nitrates are enzymatically converted to nitrites, suggesting that a UTI is present. A urine sample finding that is positive for leukocyte esterase, but negative for nitrites, may still indicate an infection.

Casts may be used to identify the location of disease in the genitourinary tract. Casts are composed of proteinaceous or fatty material that outlines the shape of the renal tubules where they are deposited. The presence of casts must be interpreted in light of other factors related to the kidney and its function; however, fatty casts, RBC casts, and WBC casts are always significant. RBC casts usually suggest glomerular injury, and WBC casts suggest tubular or interstitial injury. Lipid casts with proteinuria are characteristic findings in patients with nephrotic syndrome or hypothyroidism.[78] The finding of hyaline casts alone in the presence of proteinuria suggests a renal origin for the protein. Hyaline or granular casts alone, however, only suggest some defects in factors that affect cast formation and are therefore difficult to interpret.

Crystals may originally appear as a cloud in the urine. Their formation is pH dependent, and they often appear only as the urine cools to room temperature or in concentrated urine. In acidic urine, crystals may be uric acid or calcium oxalate; in alkaline urine, they may be phosphates. Crystals per se are not highly significant, although they may reflect a tendency toward the formation of renal calculi.

CASE 2-6

QUESTION 1: S.T. is a 33-year-old female with type 1 diabetes who presents to the urgent care clinic with a 3-day history of fever, malaise, dysuria, and flank pain. Upon interview, you learn that over the past few days, S.T. has been

unable to keep down any food because of feelings of nausea. Because of this, she has not taken her insulin for 48 hours. Today, her finger-stick blood glucose is 415 mg/dL, and a STAT midstream urinalysis and Gram stain indicate the following:

pH: 5.2
Appearance: cloudy
Specific gravity: 1.033
Urine protein: 3+
Urine glucose: 4+
Urine ketones: positive
Urine bacteria: 4+
Urine WBC: too numerous to count (TNTC)
Squamous epithelial: few per HPF
Urine nitrite: positive
Gram stain: numerous gram-negative rods

What objective data from the urinalysis indicate a UTI?

The cloudy appearance of S.T.'s urine indicates the presence of bacteria, protein, and WBCs, which is supported by the urinalysis results. The lack of a significant amount of squamous epithelial cells, the presence of a significant number of nitrite-producing bacteria, and the Gram stain indicate a clean-catch urine specimen and a UTI involving gram-negative organisms (most likely *E. coli* that causes a majority of UTIs).

Case 2-6, Question 2: What objective data from the urinalysis indicate uncontrolled diabetes?

Glucose is normally filtered in the glomerulus and a majority is reabsorbed in the proximal tubule of the kidney. S.T.'s glycosuria (4+ glucose) and finger stick of 415 mg/dL indicate the filtered amount of glucose exceeds the capacity for reabsorption (~180 mg/dL). In addition, the presence of positive ketones indicates the body is utilizing fat, not glucose, for energy. High levels of ketones can predispose S.T. to dehydration, resulting in diabetic ketoacidosis.

THERAPEUTIC DRUG MONITORING

Many drugs have a wide dosing range that can achieve efficacy with a low risk of toxicity. Drugs that have a narrow dosing range with a high risk of toxicity (narrow therapeutic index) often have their blood levels monitored. Results from therapeutic drug monitoring assist clinicians with appropriate dosing adjustments to prevent toxicity and achieve appropriate clinical outcomes. Pharmacokinetic parameters and drug interactions may significantly impact the laboratory results and must be integrated into the clinical assessment of the data. Similarly, for certain drugs and drug classes, there are recommended laboratory tests that should be performed to monitor their potential adverse effects on organ systems. Ideally, blood level monitoring should occur after the drug has reached steady state and at a consistent time within the dosing interval.

PATIENT-DIRECTED MONITORING AND TESTING

Often patient-directed self-monitoring is an essential component to successful management of certain disease states such as blood pressure monitoring for hypertension and blood glucose monitoring for diabetes mellitus. When used appropriately, data obtained from these monitoring devices can be used by health care providers and consumers to initiate or modify therapies accordingly.

Additional laboratory, self-monitoring tests or devices are also available for consumers to purchase for independent testing or screening purposes at home. Tests that are designed specifically to be used by the consumer without the involvement of a provider are called direct-to-consumer (DTC) tests. Some products provide an immediate result, whereas others require submitting a completed kit to a laboratory for analysis. Samples may be obtained from various sources, including urine, blood, saliva, stool, or hair samples. The

incidence of consumers using these products has significantly increased and likely will continue to climb because of increased access via the Internet as well as additional tests becoming available.

In the United States, some, but not all, DTC tests have been approved by the U.S. Food and Drug Administration (FDA). A current listing of approved products is available through the FDA's Office of In Vitro Diagnostic Device Evaluation and Safety (OIVD) and can be accessed online at http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/InVitroDiagnostics/default.htm. Consumers should be cautioned about the accuracy of tests that have not been approved and the validity of all test results, especially for diagnostic purposes, because many factors can impact or interfere with the sensitivity (probability of obtaining a positive result when a sample is truly positive) and specificity (probability of obtaining a negative result when the sample is truly negative). Follow-up assessment with a health care provider should be encouraged to confirm or refute patient-directed test results.

Drug Interactions

Michelle Ceresia, Caroline S. Zeind, John Fanikos, and Michael G. Carvalho

CORE PRINCIPLES		CHAPTER CASES
1	A drug interaction is either the result of pharmacokinetic changes of a drug or its metabolites owing to alteration in absorption, distribution, metabolism, or excretion or is the result of pharmacodynamic changes, impacting the effect or mechanism of action. There are several types of drug interactions. Although the classic interaction involves two drugs (drug–drug interaction or DDI), a drug interaction can involve the interaction of a drug with a nutrient, chemical, food, herbal, disease, or laboratory test.	**Case 3-1 (Questions 2–6)** **Case 3-2 (Questions 2, 3)** **Case 3-3 (Question 1), Tables 3-1, 3-3, and 3-4**
2	Some patient populations are more vulnerable to drug interactions because	**Case 3-1 (Question 1)** **Case 3-2 (Question 1)**

	of age, gender, race, and comorbidities, such as renal and hepatic insufficiency. Drugs that have a higher potential for an interaction are those with a narrow therapeutic index (NTI).	**Case 3-3 (Question 1), Table 3-2**
	PHARMACOKINETIC CHANGES	
1	Administration/absorption: Drug interactions resulting from alterations in absorption are caused by (a) changes in gastric pH, (b) formation of complexes in the gastrointestinal (GI) tract, (c) changes in GI motility, and (d) modulation of P-glycoprotein (P-gp) intestinal absorption of drugs.	**Case 3-1 (Question 1)** **Case 3-2 (Question 3), Table 3-3**
2	Distribution: Drug interactions resulting from displacement of drug bound to protein sites (eg, albumin), particularly with drugs with a high degree of plasma protein binding that are more likely to be displaced by a drug with greater affinity for the same binding site.	**Case 3-1 (Question 2), Figure 3-1, Table 3-3**
3	Metabolism: A common cause of clinically significant drug interactions during multiple drug therapy involves drug metabolism in which cytochrome P450 (CYP) isoenzymes play a significant role. Many drug interactions occur as a result of inhibition or induction of CYP enzymes.	**Case 3-1 (Questions 3, 5, 6)** **Case 3-2 (Question 2)** **Case 3-3 (Question 1), Figure 3-2, Table 3-3**
4	Excretion/elimination: Drugs are eliminated mainly through renal tubular excretion and biliary excretion. Drug	**Case 3-2 (Question 2), Table 3-3**

	interactions may occur during the elimination of drugs and their metabolites by the kidney as a result of competition at the level of active tubular secretion, interference with tubular transport, or during tubular reabsorption.	

PHARMACODYNAMICS CHANGES

1	Pharmacodynamic interactions occur when the presence of one drug changes the effect of another drug without pharmacokinetic alterations. It may be owing to competition at the drug receptor level by indirect systems, involving interference with physiologic mechanisms, resulting in additive or synergistic interactions or antagonistic interactions.	**Case 3-1 (Question 4)** **Case 3-2 (Questions 2, 3), Table 3-4**

RESOURCES AND EVIDENCE FOR CLINICAL DECISION SUPPORT

1	Patient safety initiatives have expanded in efforts to improve the health care delivery system with medication error prevention as a high-priority area. Health care providers have become increasingly challenged on devising optimal approaches to managing drug interactions. A key challenge is that computerized drug interaction screening systems detect a large number of DDIs of questionable clinical significance. Expert groups have provided recommendations to improve the	**Case 3-1 (Question 6)**

usability of clinical decision support (CDS) alerts for managing drug interactions.

INTRODUCTION

Because health care professionals are committed to ensuring patient safety and preventing drug-related harm, it is important to understand drug interaction principles and how to apply drug interaction decision support tools to provide evidence-based clinical decisions. This chapter introduces the reader to general principles and concepts of drug interactions. Case studies are incorporated to illustrate the application of key concepts and to highlight the importance of understanding the mechanisms by which drugs interact and how it impacts the clinical assessment and management of drug therapy. Disease-specific chapters within this textbook will also apply drug interaction concepts and incorporate case studies relevant to disease management.

DEFINITION

Drug interactions can be broadly categorized as either pharmacokinetic or pharmacodynamic in nature.[1,2] Pharmacokinetic drug interactions involve absorption, distribution, metabolism, and excretion, whereas pharmacodynamic interactions can be characterized into three subgroups: (a) direct effect at receptor function, (b) interference with a biologic or physiologic control process, and (c) additive or attenuated pharmacologic effect.[3] Another key area of consideration is the biologic variance in a given individual: genetics, age, disease, and the internal environmental factors (ie, the patient's medications, dietary intake, and social habits such as smoking and alcohol consumption).[4]

A *drug–drug interaction* (DDI) is defined "as a clinically meaningful alteration in the exposure and/or response to a drug (object drug) that has occurred as a result of the coadministration of another drug (precipitant drug)."[1–2,5,6] Drug interactions may have beneficial effects because some drug interactions are used to enhance therapeutic outcomes, whereas other interactions may have deleterious effects that result in serious toxicity or may inhibit the effects of a drug, leading to suboptimal therapeutic outcomes. Although the classic interaction involves two drugs (DDI), a drug interaction can involve the interaction of a drug with a nutrient, chemical, food, herbal, disease, or laboratory test.[7,8] A *potential drug interaction* is defined "as the occurrence in which two drugs that are known to interact are concurrently prescribed, regardless of whether adverse events occurred."[8]

In 2015, consensus recommendations for evaluating DDIs were published by an expert group that included definitions of relevant terminology for evaluation of DDI evidence.[5] **Table 3-1** highlights their recommendations for key terms of relevant terminology for evaluation of DDI evidence. (The reader is referred to the complete list of definitions agreed upon by this expert group that are provided in their supplementary publication.)[5] They emphasize the importance of consistent use of relevant terminology for evaluation of DDI evidence. For example, a clinically relevant DDI is defined as one that is associated with either toxicity or loss of efficacy that warrants the attention of health care professionals.[2]

Table 3-1
Terminology Related to DDI

Terminology	
DDI	Clinically meaningful alteration in the exposure and/or response to a drug (object drug) that has occurred as a result of the coadministration of another drug (precipitant drug)
Potential DDI	Coprescription of two drugs known to interact; therefore, a DDI could occur in the exposed patient.
Clinically relevant	Drug–drug interaction associated with either toxicity or loss of efficacy that warrants the attention of health care professionals

DDI	
NTI drugs	Drugs for which even a small change in drug exposure may lead to toxicity or loss of efficacy

DDI, drug–drug interaction; NTI, narrow therapeutic index.

Source: Adapted by permission from Springer. Scheife RT, Hines LE, Boyce RD, et al. Consensus recommendations for systematic evaluation of drug-drug interaction evidence for clinical decision support. *Drug Saf*. 2015;38(2):197–206.

The Food and Drug Administration (FDA) has now provided guidance to evaluate DDIs as part of a company's assessment of the drug's benefits and risks during the drug development process.[9] Clinically relevant DDIs should be recognized at the time of drug approval, monitored after approval, and communicated in the package labeling. Studies will be completed to determine whether cytochrome P450 (CYP) enzyme- and transporter-mediated DDIs alter the pharmacokinetics of new drug or the pharmacokinetics of other drugs. Studies will also determine the clinical significance of the observed or expected DDIs and any appropriate management or prevention strategies. Because known agents will be used to determine whether a new medication is a victim or perpetrator of DDIs, clinicians can expect to see a list of common offending medications reported in the package labeling.

RISK FACTORS FOR DRUG INTERACTIONS

Some patient populations are more vulnerable to drug interactions because of age, gender, and comorbidities, such as renal and hepatic insufficiency. Polypharmacy, defined as the concomitant use of multiple drugs or the administration of more medications that are indicated clinically, is a leading cause of DDIs, resulting in higher rates of adverse events, higher drug costs, and medication nonadherence.[10–12] Elderly patients are at an increased risk of drug interactions given the rates of polypharmacy (estimated at 20%–50%) in the older population, along with multiple comorbidities.[13–15]

Adverse drug reactions (ADRs) have been observed two to three times more frequently in older persons and account for 5% to 17% of all hospital admissions.[16] Age alone is a key risk factor in the elderly population as altered pharmacokinetics and pharmacodynamics may result in a slower intestinal transit time, diminished absorption capacity, decreased liver metabolism and renal excretion, and alterations in volemia and body fat distribution.[17,18] Within the older population, the frail elderly represents a subgroup in which comorbidities primarily account for the observed changes in pharmacokinetic and pharmacodynamic properties.[13] When considering the impact of aging, it is important to differentiate the subgroup of fit elderly from that of the frail elderly, because those who are frail are at increased risk of death, institutionalization, and worsening disability.[13,19,20] A number of studies have shown that females are at higher risk for drug interactions.[21–24] Further research is needed in this area to better understand gender differences with drug interactions.[21–24] The distribution of many drugs may be significantly altered because of marked increases in total body weight (TBW).[25] Drugs that are lipophilic will have an increased volume of distribution. Patients who are obese and those who are malnourished will have altered levels of metabolizing enzymes, increasing their susceptibility to drug interactions.[16,26] Critically ill patients, those with poor nutritional status, and patients who are immunocompromised are at higher risk of drug interactions. Cigarette smoking can affect drug therapy by both pharmacokinetic and pharmacodynamic mechanisms. It can affect drug therapy by enzyme induction of CYP; enzymes induced by tobacco smoking may also increase the risk of cancer by enhancing metabolic activation of carcinogens.[27] Drugs that have a higher potential for an interaction are ones with a narrow therapeutic index (NTI) because there are small differences between therapeutic and toxic doses. For example, lithium, a monovalent cation, is a drug with an NTI that is influenced by changes of serum sodium. Patients taking lithium and who are also receiving chronic treatment with thiazides are at risk of lithium toxicity because thiazides can cause a high excretion of sodium that may increase lithium reabsorption.[3]

An individual's genetic makeup determines their complement of metabolizing enzymes, and based on their genotype, patients may be classified as having a phenotype for ultrarapid metabolizer, extensive metabolizer, intermediate metabolizer, or poor metabolizer (refer to Chapter 4, Pharmacogenomics and Personalized Medicine).[28] Individuals who use multiple providers and/or multiple pharmacies are more likely to have incomplete information available for both the providers and themselves; this impacts clinical decision-making and increases the likelihood that a drug interaction may go undetected. Individuals who self-prescribe and take over-the-counter (OTC) products (including dietary supplements, vitamins, minerals, and herbal agents) may not understand the potential risk for drug interactions. In addition, if they do not maintain a complete listing of OTC products for themselves and their providers, there is a greater likelihood for ADRs and drug interactions. Although disease-specific chapters in this textbook will provide a wide array of risk factors for drug interactions, **Table 3-2** outlines examples of risk factors for drug interactions.

Table 3-2
Risk Factors for Drug Interactions[1,13–34]

Category	Risk Factor	Potential Effect
Patient characteristics Demographics	Age (<5 years and ≥65 years)	Alterations in drug distribution; ↓ clearance that may result in drug accumulation
	Female gender	↓ Ability to metabolize compared to males
Social factors	Nutrition	Affects cytochrome p450 (CYP) activity (eg, grapefruit juice inhibits CYP3A4 activity)
	Smoking	Affects CYP activity (ie, induces CYP1A2)
	Alcohol	Affects CYP activity, specifically CYP2E1
Organ dysfunction	↓ Renal function	↓ Clearance, which may result in ↑ serum concentrations of drug

		and accumulation
	↓ Hepatic function	↓ Metabolism, which may result in ↑ serum concentrations and accumulation of the parent drug and/or metabolite
	Heart failure (HF)	↑ Risk owing to the number of medications prescribed with comorbidities
	Chronic obstructive pulmonary disease (COPD)	↑ Risk owing to the number of medications prescribed with comorbidities
Metabolic and endocrine	Obesity	↑ Distribution of lipophilic drugs
	Fatty liver	Altered metabolism
	Hypoproteinemia	↑ Serum drug concentration
Genetic[a]	Genetic polymorphisms (ultrarapid, extensive, intermediate, or poor metabolizers)	Altered metabolism
Acute medical conditions	Dehydration	↑ Serum drug concentrations
	Hypotension	↓ Clearance
	Hypothermia	↓ Clearance
	Infection	↑ Catabolism
Drug characteristics	Narrow therapeutic index (NTI)	↑ Risk of dose-related adverse drug events
	Highly protein bound	↑ Free fraction (active drug) from protein displacement
	Small volume of distribution	Drug confined to the plasma
	CYP substrate	↓↑ Serum drug concentration with coadministration of inducer or inhibitor precipitant drug
	P-glycoprotein substrate	↓↑ Serum drug concentration with coadministration of inducer or inhibitor precipitant drug
Other factors	Polypharmacy	Risk of adverse drug interactions ↑ with increase in number of medicines

	Number of prescribers	Number of prescribed drugs ↑ with multiple prescribers
	Number of pharmacies utilized	Number of prescribed drugs ↑ with multiple pharmacies Pharmacist may not have knowledge of all drugs prescribed to patient.
	Self-prescribing	OTC medicines interacting with prescribed medicines
	Duration of hospital stay	Susceptible to hospital-acquired conditions and subsequent drug therapy

OTC, over-the-counter.

[a]Refer to Chapter 4, Pharmacogenomics and Personalized Medicine for further information.

CASE 3-1

QUESTION 1: F.D. is a 79-year-old female patient who underwent a total hip replacement at a large teaching hospital. The medical team plans to start F.D. on warfarin therapy for venous thromboembolism prophylaxis with an international normalized ratio (INR) target range of 1.8 to 2.3 for a total duration of 3 weeks. The first dose will be administered in the evening on the day of surgery.

Her medical history includes newly diagnosed osteoporosis, recently started on alendronate; epilepsy that developed several years ago, controlled with phenytoin; and hypercholesterolemia for the past 9 years, for which she takes fluvastatin. She does not drink alcohol and has never smoked. She takes an OTC medicine, but does not recall the name of the product. She has some renal dysfunction (creatinine clearance 70 mL/minute). Her hepatic function is within normal range. F.D. requests that the medical team electronically transmit her new prescriptions postdischarge to a pharmacy located in close proximity to her friend's home because she will be recuperating there.

What are F.D.'s risk factors for drug interactions with the addition of warfarin postsurgery?

F.D. has multiple factors including patient- and drug-specific ones that increase her risk for drug interactions. Her patient risk factors include age, gender, and renal dysfunction.

Patient Risk Factors

- Older age: 79 years old—altered pharmacokinetics and pharmacodynamics
- Female gender: decreased ability to metabolize compared to males
- Renal dysfunction: decreased clearance of renally eliminated medications, which may result in increased serum concentrations of drug and accumulation

With regard to drug-specific factors, F.D. has been taking phenytoin, a drug with an NTI, for the past several years. She will be receiving warfarin, another agent with NTI. Both medications are metabolized via the CYP system. In addition, F.D. is at increased risk of additional drug interactions owing to polypharmacy because she has chronic disease comorbidities (ie, seizure disorder, hypercholesterolemia, and osteoporosis).

Drug Risk Factors

- Warfarin—NTI, highly protein bound to albumin, small volume of distribution, metabolized by the CYP system
- Phenytoin—NTI, highly protein bound to albumin, metabolized by CYP2C9 and CYP2C19 isoforms, and susceptible to drugs that inhibit hepatic microsomal enzymes
- Fluvastatin and other agents in this class (eg, atorvastatin, rosuvastatin, and simvastatin)—suspected or known to alter the INR in patients who receive warfarin, whereas pravastatin does not appear to interact with warfarin[35–37]
- Unknown OTC product

Other Risk Factors

- Polypharmacy—before admission, she is already taking three prescription drugs and also takes OTC products. She is a poor historian.

- Number of pharmacies used—pharmacist may not have knowledge of all drugs prescribed to patient.

MECHANISMS OF DRUG INTERACTIONS

Pharmacokinetics

ADMINISTRATION/ABSORPTION

Following oral administration, most drug absorption occurs in the proximal small intestine.[38] However, drug interactions that alter absorption may occur throughout the gastrointestinal (GI) tract by a variety of mechanisms, including complexation (adsorption or chelation), changes in pH, changes in GI motility, altered drug transport, and enzymatic metabolism. The net effect of one or more of these mechanisms is a change in the rate of absorption, the extent of absorption, or a combination of both. Although interactions that result in a reduced rate of absorption are generally not clinically significant for drugs given over the long term in multiple doses, for acutely administered drugs, such as analgesics or hypnotics, this can lead to an unaccepted delay or therapeutic failure.[1,39]

With regard to changes in gastric pH, the majority of drugs that are orally administered must be dissolved and absorbed in a gastric pH between 2.5 and 3. Drugs, such as antacids, proton-pump inhibitors (PPIs), or H_2-antagonists, can alter the kinetics of coadministered drugs.[3] Antifungal agents, such as ketoconazole or itraconazole, require an acidic environment to be properly dissolved. Coadministration with drugs that increase gastric pH may cause a reduction in the dissolution and absorption of antifungal drugs. It is recommended that these antifungal agents be administered at least 2 hours after the administration of antacids.

Coadministration of medications around the same time can result in drug interactions that may be clinically significant. Some antibiotics, such as tetracyclines, will combine with metal ions (eg, calcium, magnesium, aluminum, iron) to form complexes that are

poorly absorbed. Antacids also reduce the absorption of fluoroquinolones (eg, ciprofloxacin) because the metal ions form complexes with the drug. Therefore, the antacids and fluoroquinolones should be administered at least 2 hours apart. These types of interactions can decrease clinical effectiveness of the antibiotic and can lead to the emergence of resistant organisms.[34] Drugs that are able to increase the gastric transit, such as metoclopramide owing to its prokinetic properties, may accelerate gastric emptying, resulting in decreased absorption of drugs, such as digoxin or theophylline.

Altered drug transport

Transport proteins, which are present in the intestinal mucosa, are important considerations in clinically relevant DDIs.[38] Some proteins are involved in the transport of compounds from the lumen of the intestine into the portal bloodstream, whereas others are involved in the efflux of compounds from the intestinal mucosa back into the gut lumen. The efflux transporters, particularly a specific glycoprotein, which resides in the cell membrane, P-glycoprotein (P-gp), are the most well known. P-gp is an adenosine triphosphate (ATP)-dependent transporter that is genetically encoded and located on the apical surface of mucosal cells in the intestine, generally in increasing concentration from the stomach to the colon. In addition, P-gp is also present on a number of lymphocyte subsets and within the brain capillary endothelial cells. The primary role of P-gp is to limit systematic drug exposure, pumping compounds from the inside of the cell back into the gut lumen, into renal tubules in the kidney, and into bile in the liver. Given its presence in various anatomic locations, drug-induced modulation of P-gp activity may affect the absorption and/or distribution of a coadministered substrate medication. There are several drugs that are known to block the action of P-gp and are known as P-gp inhibitors, and there are drugs that have been shown to cause induction of P-gp. Coadministration of a P-gp substrate with an inhibitor increases the amount of substrate available for absorption and may result in an elevated

serum drug concentration. For drugs such as rifampin that increase expression of P-gp (ie, P-gp inducer), the coadministration of a substrate results in an enhanced efflux of the substrate into the gut lumen and lowers serum concentration of the substrate.

DISTRIBUTION

CASE 3-1, QUESTION 2: What is the interaction of warfarin and phenytoin based on protein binding?

Following administration and absorption, drugs are distributed throughout the body.[38,39] Drugs such as warfarin and phenytoin are highly bound to protein (primarily to albumin) with the same affinity binding sites (**Fig. 3-1**). Drugs that are highly protein bound (>90%), those with an NTI, and those with a small volume of distribution are more likely to result in significant drug interactions.

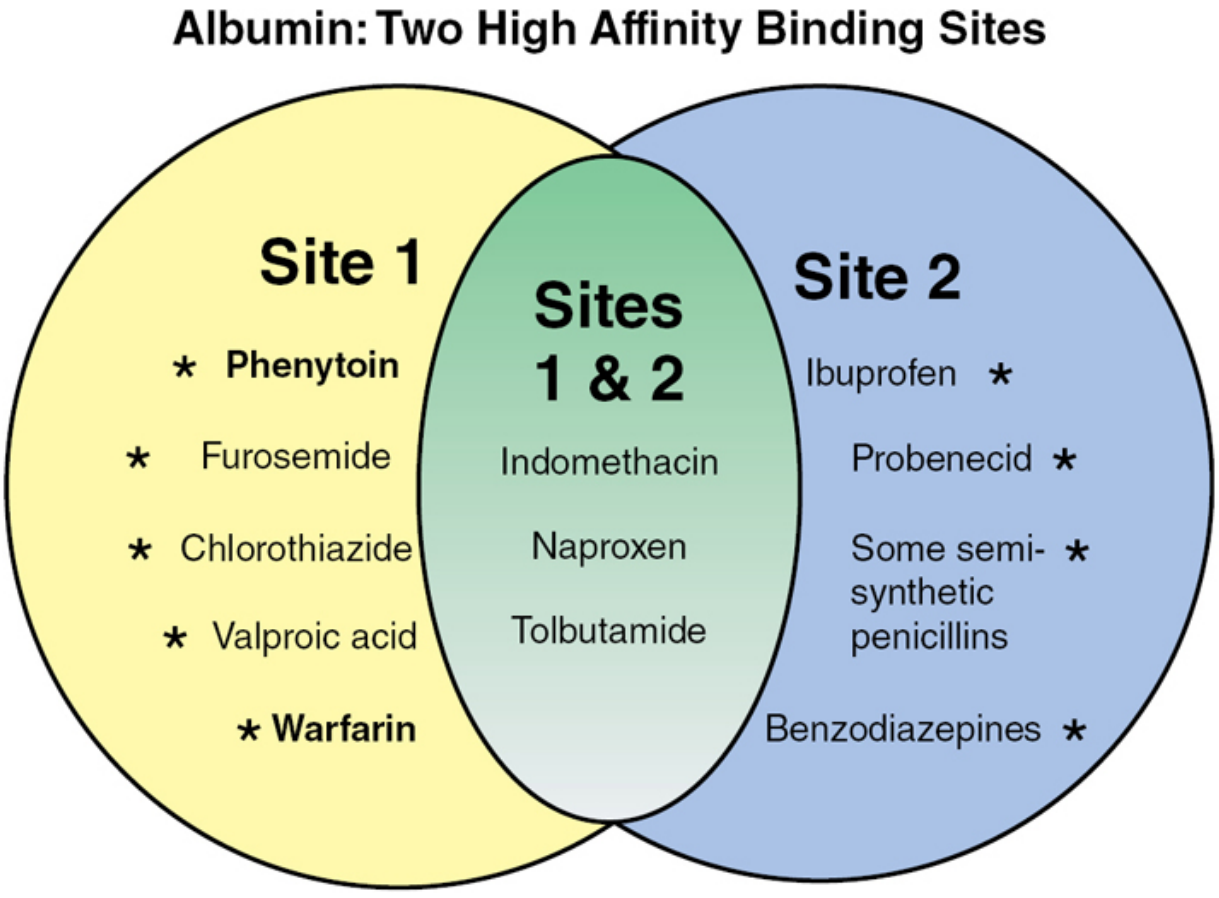

Figure 3-1 Examples of drugs that bind to and compete for one of two sites, designation I and II, on albumin. (Adapted with permission from Drug interactions. In: Derendorf H, Schmidt S, eds. *Rowland and Tozer's Clinical Pharmacokinetics and Pharmacodynamics: Concepts and Applications*. 5th ed. Wolters Kluwer; 2020.)

Warfarin can be displaced from protein-binding sites by drugs such as phenytoin. Although this displacement occurs quickly with rapid changes in serum warfarin levels, typically, this interaction is not clinically significant. Warfarin that is displaced from protein-binding sites is readily available for elimination by hepatic metabolism, resulting in increased clearance without a significant change in the free drug concentration. Because warfarin's anticoagulant action takes several days because of the long half-lives of some of the vitamin K–dependent clotting factors, warfarin equilibrium is reestablished before a new steady state can be reached for these clotting factors.[33]

METABOLISM

Pharmacokinetic interactions that involve changes in metabolism are a common cause of clinically significant drug interactions. Drug metabolism is divided into two general categories: phase I and phase II reactions.[38,39] Phase I reactions involve intramolecular changes including oxidation, reduction, and hydrolysis, which increases the polar nature of the drug, generally making it less toxic. Phase II reactions generally involve combining a phase I product with an endogenous substance, resulting in glucuronidation, sulfation, acetylation, and methylation, and primarily results in termination of biologic activity of the drug.[40,41] The main enzymes that are responsible for drug-metabolizing systems in phase I reactions are the CYP enzymes, which play a key role in many therapeutically important drug interactions.[1,2] Drugs that are metabolized by the same CYP enzyme family, when administered concurrently, may interact with each other as a result of induction or inhibition.[40,41] Of the human CYP enzyme family, the six isoenzymes CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP3A4, and CYP3A5

contribute to the metabolism of a vast majority of drugs compared with other enzymes (**Fig. 3-2**).[6,42–44] Examples of drug that induce enzymes are rifampin, phenytoin, carbamazepine, St. John's wort, and nevirapine. Enzyme inducers cause an increase in the synthesis of the enzyme(s) responsible for metabolism of the substrate drug. The mechanisms of induction are complex involving presystemic metabolism via induction of hepatic and/or intestinal drug–metabolizing enzymes, subsequently reducing serum concentrations with a loss of pharmacologic activity of the drug. In some cases, induction will increase the formation of metabolites that are pharmacologically or toxicologically active.[1,44,45] There are many drugs that are inhibitors of CYP including some drugs within these classes: statins, macrolide antibiotics, antifungal azoles, fluoroquinolones, and HIV protease inhibitors. Inhibition of drug metabolism slows down the rate of drug metabolism, resulting in an increase in the amount of drug in the body and potential toxicity. Grapefruit juice is an inhibitor of CYP3A4 and has been known to increase the bioavailability and reduce the clearance of many drugs, including HMG-CoA reductase inhibitors (statins), calcium antagonists, HIV protease inhibitors, and immunosuppressant agents.[46–49] Inhibition can be described as reversible or irreversible, with the reversible ones being a more common process. There are three mechanisms of reversible inhibition: competitive inhibition (competition between the inhibitor and the substrate for the enzyme's active site), noncompetitive inhibition (binding of the inhibitor to a separate site on the enzyme, rendering the enzyme complex nonfunctional), and uncompetitive inhibition (binding of the inhibitor only to the substrate–enzyme complex, rendering it ineffective).[1,49,50] Irreversible inhibition occurs when the perpetrator drug forms a reactive intermediate with the enzyme that leads to a permanent inhibition of the enzyme. Irreversible drug interactions tend to be more profound than those caused by reversible mechanisms. Examples of drugs that are known to cause irreversible inhibition include macrolide antibiotics, erythromycin, clarithromycin, paroxetine, and diltiazem.[16,51,52]

CASE 3-1, QUESTION 3: The medical team starts warfarin therapy for F.D. for postoperative thromboembolism prophylaxis. What are the mechanisms of drug interactions to consider with the use of warfarin and phenytoin because F.D. has been taking phenytoin for several years and her seizure disorder has been controlled on it?

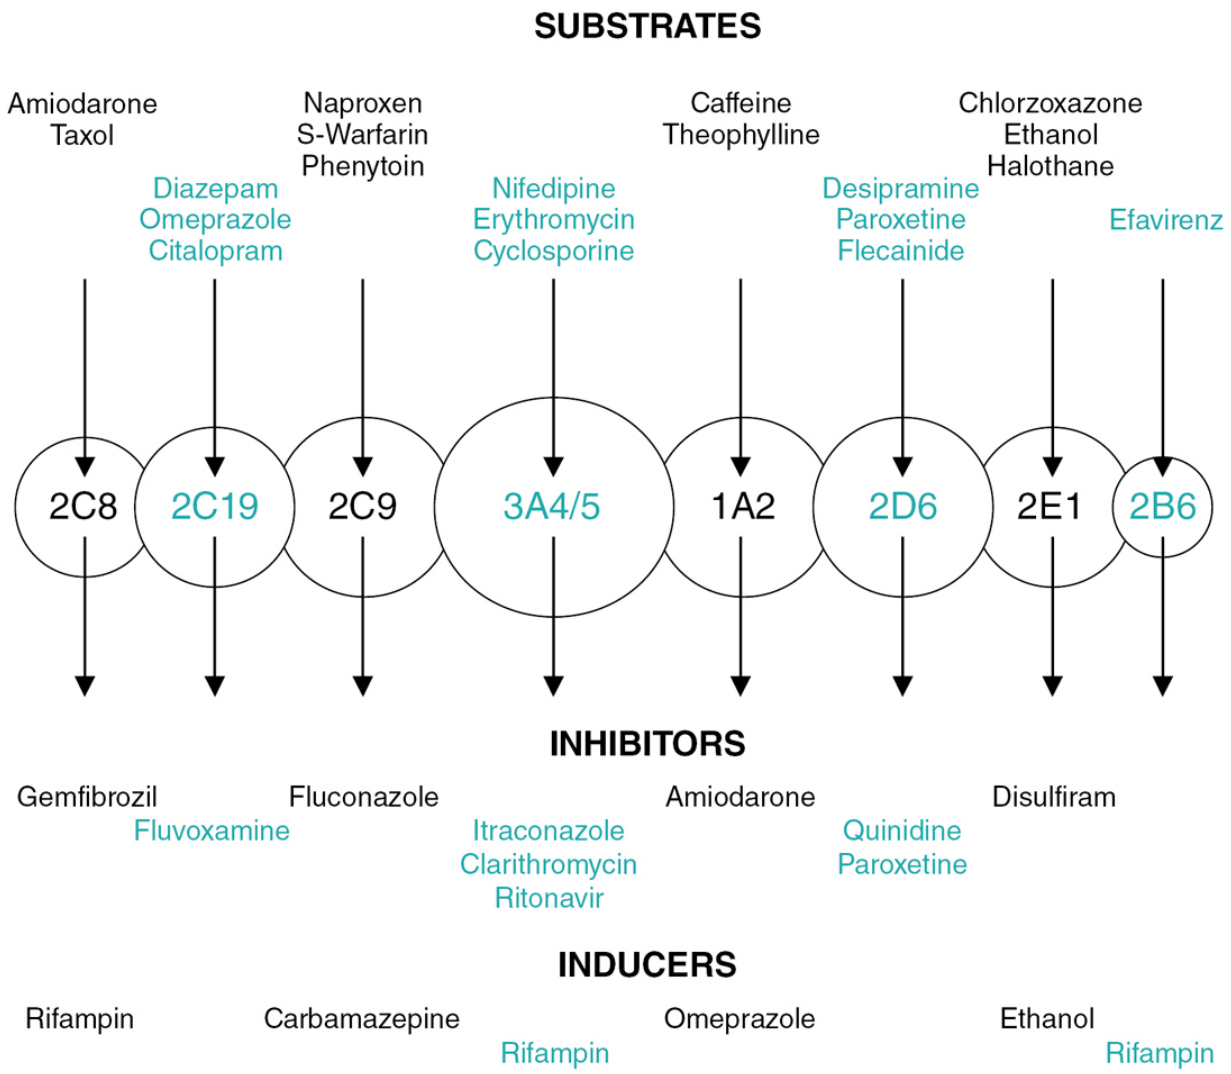

Figure 3-2 Graphic representation of the different forms of cytochrome P450 (circles) in humans with different but some overlapping substrate specificities. The arrows indicate single metabolic pathways. Representative substrates are listed for each enzyme. Also listed are relatively selective inhibitors and inducers of the enzymes. (Reprinted with permission from Drug interactions. In: Derendorf H, Schmidt S, eds. *Rowland and Tozer's Clinical*

Pharmacokinetics and Pharmacodynamics: Concepts and Applications. 5th ed. Wolters Kluwer; 2020.)

There are two potential mechanisms for a warfarin (drug)–phenytoin (drug) interaction. In early therapy, there could be a displacement of warfarin from protein-binding sites by phenytoin (as described in the previous case question) and a possible enhancement of the anticoagulant effect and risk for bleeding. This is primarily a concern in patients with hepatic impairment. With prolonged therapy, there could be a phenytoin-induced CYP enzyme induction, thereby enhancing warfarin metabolism, resulting in a decreased warfarin effect. INR monitoring on postoperative days 1 through 5 will provide information on the impact of the DDI, and incorporation of a warfarin initiation guideline or algorithm will help adjust dosing until a stable regimen is established. After the initial period, weekly INR monitoring will provide information on enzyme induction and further adjustment of warfarin doses.

Warfarin is rapidly and completely absorbed after oral administration, with the proximal duodenum appearing to be the most likely location of absorption. Case reports of warfarin malabsorption, whether acquired, related to surgery, or inflammatory conditions, are rare.[53]

The rate and extent of phenytoin absorption varies considerably among oral dosage forms.[54] Phenytoin suspension is poorly absorbed when administered via feeding tube with continuous enteral feedings.[55] The time to reach maximum plasma levels increases with increasing dose.[56] This is a reflection of low phenytoin solubility and capacity-limited metabolism. Therefore, a small change in the dosage form or bioavailability, coupled with limited metabolism, can produce a large change in plasma drug concentration.[57] GI surgery and GI inflammatory conditions (Crohn disease, ulcerative colitis, scleroderma, etc.) can change the anatomy of the GI tract. Alterations to surface area, gastric emptying time, gastric pH, and inflammation of the intestinal lining may lead to abnormal plasma concentrations.[58]

F.D.'s GI function is still preserved after orthopedic surgery. Warfarin administration and absorption is unlikely to be impacted. She should continue on the same phenytoin dose and formulation that she has been taking at home with appropriate monitoring.

Pharmacokinetic interactions influencing the metabolism of warfarin and clinically significant interactions are likely with warfarin use when its metabolism is induced or inhibited.[49] Warfarin is a racemic mixture of *R*- and *S*-enantiomers. Interactions involving agents known to influence the hepatic microsomal enzyme systems responsible for the metabolism of the more potent *S*-enantiomer (CYP2C9) are more significant than those that influence the enzymes that metabolize *R*-enantiomer (CYP1A2, CYP3A4). Phenytoin is also predominately metabolized via the CYP2C9 enzyme and has been reported to interact with warfarin in a biphasic manner.[50–52]

Genetic polymorphism also is a significant factor affecting warfarin dosing and response. Nucleotide polymorphisms have been identified that influence warfarin metabolism and sensitivity, including variants of CYP2C9 and variants in vitamin K epoxide reductase complex (*VKORC1*).[59]

EXCRETION/ELIMINATION

Drugs are excreted and eliminated mainly via the kidneys (glomerular filtration, tubular reabsorption, and active tubular secretion); other important, though less common, routes are via biliary secretion, plasma esterases, and other minor pathways. Drug interactions may occur during the elimination of drugs and their metabolites by the kidney as a result of competition at the level of active tubular secretion, interference with tubular transport, or during tubular reabsorption.

Urinary alkalinization and acidification by some drugs can affect the excretion of other drugs changing their elimination rate. For example, the use of probenecid, a potent inhibitor of the anionic pathway of renal tubular secretion, increases the serum

concentration of penicillins, which can be used for therapeutic purposes.

Pharmacodynamics

Pharmacodynamic interactions occur when the response of one drug is modified by the presence of another one without alterations in pharmacokinetics. These types of interactions may be predicted if the pharmacologic effects of a drug are known, and the patient response may be additive or antagonistic.[2,8] For example, there may be an interaction in which one drug, an angiotensin-converting enzyme (ACE) inhibitor, and another drug, a thiazide diuretic, each act by a different mechanism of action to lower blood pressure (BP), producing an exaggerated hypotensive effect.

Case 3-1, Question 4: What pharmacodynamic interactions are clinically relevant to warfarin?

Pharmacodynamic interactions with warfarin are those that alter the physiology of hemostasis, particularly interactions that influence the synthesis or degradation of clotting factors or that increase the risk of bleeding through inhibition of platelet aggregation. In patients receiving warfarin, the addition of any drugs that increase or decrease clotting factor synthesis, enhance or reduce clotting factor catabolism, or that impair vitamin K production by normal flora will increase the risk of drug interactions.

Tables 3-3 and **3-4** provide examples of common mechanisms of pharmacokinetic and pharmacodynamic drug interactions, respectively.

Table 3-3
Common Mechanisms of Pharmacokinetic Drug Interactions[1,3,6,17,32–34,38,60–65]

	Mechanism	Example

	Mechanism	Example
Pharmacokinetics: administration/absorption	Drugs that alter the pH of the stomach can affect absorption of other drugs	Itraconazole requires an acidic gastric pH to become soluble; absorption may be decreased if a patient is taking a drug that increases gastric pH such as a PPI or H_2-blocker.
	Induction or inhibition of CYP enzymes in the GI tract	Grapefruit juice inhibits intestinal CYP3A4, potentially increasing the bioavailability of CYP3A4 substrates such as nifedipine and verapamil.
	Induction or inhibition of P-gp (an efflux pump that expels drugs) in GI tract	Dabigatran, a substrate for P-gp, peak concentrations may be increased by P-gp inhibitors (eg, ketoconazole, clarithromycin, amiodarone), leading to a significantly increased risk of bleeding.
	Increase or delay gastric emptying/motility	Erythromycin, a potent prokinetic agent, is a motilin receptor agonist that increases gastric motility; absorption of coadministered drugs may be affected.
	Killing enteric bacteria	Antibiotics can kill bacteria that produce deconjugating enzymes; drugs that undergo enterohepatic circulation such as birth control pills may have decreased blood concentrations and half-life because of increased excretion in the feces.
	Chelation	Cations such as aluminum or magnesium antacids decrease the GI absorption of tetracycline antibiotics by forming drug–metal complexes.

	Mechanism	Example
	Physiochemical inactivation	Mixing a furosemide solution with an acidic solution (ie, with midazolam) decreases the pH sufficiently to cause furosemide precipitation and reduced availability when administered intravenously.
Pharmacokinetics: distribution	Interaction between two highly protein-bound drugs (eg, a precipitant drug has stronger affinity for the same protein-binding site)	Sulfamethoxazole displaces warfarin from protein-binding sites, increasing the free fraction. Sulfamethoxazole also inhibits the metabolism of warfarin. As a result, the body cannot compensate to increase the elimination of the high free (active) fraction of warfarin. The end result is likely an increase in the INR and potential risk for bleeding. See Chapter 11 for detailed warfarin–sulfamethoxazole drug interaction.
	Inhibition of carrier proteins such as P-gp located in blood–brain barrier and OATPs located in the liver	Cyclosporine may inhibit the transporter OATP1B1, decreasing the hepatic uptake of most statins; efficacy of the statin may be lost because the site of action is located in the liver.
Pharmacokinetics: metabolism	Induction or inhibition of CYP enzymes in the liver	*Example 1:* Fluoroquinolones inhibit metabolism of theophylline via CYP1A2 enzyme; the extent of the interaction varies between the different fluoroquinolones. *Example 2:* Rifampin has a half-life of 4 hours; however, time to steady-state induction with propranolol does not occur until 10–14 days.

	Mechanism	Example
Pharmacokinetics: excretion/elimination	Administration of two drugs that use the same transport system and undergo active tubular secretion by the kidneys	Methotrexate clearance may be reduced in the presence of salicylates. Salicylates decrease renal perfusion via PGE_2, having the potential to cause renal impairment and competitively inhibit the tubular secretion of methotrexate.
	Increased or decreased renal tubular absorption	*Example 1:* Alkalization of the urine with sodium bicarbonate will decrease the reabsorption of acidic compounds such as salicylates, a treatment in overdose. *Example 2:* Thiazide diuretics initially cause sodium excretion, followed by compensatory sodium reabsorption. Administered with lithium, a cation can cause increased lithium reabsorption and possible toxic concentrations.

GI, gastrointestinal; INR, international normalized ratio; OATP, organic anion transporting peptide; P-gp, P-glycoprotein; PPI, proton-pump inhibitor.

Table 3-4
Common Mechanisms of Pharmacodynamic Drug Interactions[66]

	Mechanism	Example
Pharmacodynamics	Additive—two or more medications with comparable pharmacodynamic effects result in an exaggerated and/or toxic response	An adverse effect of each of the drugs, clarithromycin and saquinavir, is QTc prolongation. Administration of them together increases the risk for QTc prolongation and an increase in plasma concentrations.

	Mechanism	Example
	Antagonistic—the effects of one drug oppose the actions of another drug	*Example 1:* Antagonism at the same receptor site: reversal of benzodiazepines with flumazenil *Example 2:* Opposing pharmacodynamics actions: glucocorticoids cause hyperglycemia opposing the effects of hypoglycemic medications.

MANAGEMENT OF DRUG INTERACTIONS

CASE 3-1, QUESTION 5: The medical intern on the team also plans to prescribe a combination analgesic (oxycodone/acetaminophen) in place of intravenous (IV) morphine for the pain management.

In addition, F.D. remembers St. John's wort is the name of the OTC product that she takes. She said it helps with her seasonal depression.

As the pharmacist on the multidisciplinary team, your role is to assess therapy and make recommendations as needed. What recommendations regarding F.D.'s therapy do you make, including the use of St. John's wort?

Although acetaminophen is a commonly used nonprescription analgesic and antipyretic medication for mild-to-moderate pain and fever, its presence is often unrecognized in combination products containing opioids prescribed for moderate-to-severe pain. Several studies have identified acetaminophen as a culprit drug in potentiating the effects of warfarin.[67,68] Patients who take four 325-mg acetaminophen tablets per day for longer than a week were more likely to have an INR >6.0 than those who did not take acetaminophen.

There is no evidence for a pharmacokinetic interaction between acetaminophen and warfarin.[69] However, acetaminophen is

metabolized by CYP2E1, producing the metabolite *N*-acetyl-*p*-benzoquinone-imine (NAPQ1). NAPQ1 oxidizes vitamin K-hydroquinone (KH2), the "active" form of vitamin K, and directly inhibits vitamin K–dependent carboxylation.[70] There may be other oxidative changes, producing enzymatic disruption, that impact vitamin K synthesis and activity. The end result is an exaggerated response to warfarin and an increased INR.

Therefore, if F.D. is to be placed on oxycodone/acetaminophen therapy, her INR should be monitored more frequently and her dose adjusted accordingly. This is important particularly if she requires higher sustained doses of warfarin.

Dietary supplements, including herbal medicinals, amino acids, and other nonprescription products, are not tested before marketing for interactions with other medications, including warfarin. Little is known about their interactive properties, other than published case reports of varying quality. In addition, dietary supplements are not required to meet U.S. Pharmacopeia standards for tablet content uniformity.

St. John's wort, an herb whose yellow flowers and leaves are used to make herbal supplements, has been used for the treatment of depression. It has also been shown to lower patient INR values and potentially decrease warfarin's effectiveness.[71,72] Although this interaction is probably because of the induction of CYP2C9, the degree of induction is unpredictable owing to variable quality and quantity of the herbal constituent in the preparations. Similarly, St. John's wort has been suspected of reducing phenytoin plasma concentrations through induction of CYP3A4.

The addition of St. John's wort to F.D.'s current drug regimen would not be advisable because it would increase her risk for drug interactions. The implications for initiating St. John's wort in F.D. would require measurement of phenytoin and more frequent INR testing to ensure a new steady state for each agent has been reached. At this point, it is important to assess F.D.'s depression and to evaluate therapeutic options that would provide the least risk of drug interactions, as well as psychosocial treatment.

Case 3-1, Question 6: The medical team would like to resume F.D.'s medications that she was taking before admission. However, when the medical resident enters the order into the computer, they receive an electronic health record drug interaction alert regarding the statin and warfarin. How should this be managed?

Fluvastatin is metabolized extensively by the CYP system, primarily by CYP2C9 and to a lesser extent by CYP3A4 and CYP2C8. Fluvastatin is also a substrate for the transport protein OATP1B3. OATP transports statins from the blood to the liver for metabolism or excretion into the bile and feces. The combination of fluvastatin and warfarin has resulted in an increase in the INR, hence increasing the risk of bleeding.[3,35,36] In addition to this, fluvastatin when coadministered with phenytoin has been reported to increase phenytoin serum concentrations.[73] Each of the statin agents is metabolized by different CYP isoenzymes and to different degrees (**Table 3-5**). The goal of lipid management is to prescribe an agent with the least side effects and at the lowest effective dose. If a patient, such as F.D., requires a drug that interacts with statin metabolism (CYP), switching to a statin that has a more favorable elimination profile may be the best option. For example, pravastatin is a good alternative because its elimination is not dependent on CYP metabolism and is eliminated 20% by the renal route.[74] F.D. has minor renal dysfunction with a creatinine clearance of 70 mL/minute; pravastatin would not require dose adjustment unless F.D.'s glomerular filtration rate (GFR) drops <30 mL/minute.[75] However, if fluvastatin is continued with warfarin therapy more frequent, monitoring of the INR is recommended until a stable INR has been reached. It is vital to monitor the patient's INR during initiation and discontinuance of fluvastatin therapy.[73] Table 3-5 provides a summary of the metabolism of HMG-CoA reductase inhibitors.[36,74,76,77] Refer to Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease, for more information on the use of statins, including drug interactions.

Table 3-5
Transport, Metabolism, and Excretion of HMG-CoA Reductase Inhibitors (Statins)

Statins	Transport Protein[a]	Isoenzyme	Renal Excretion (%)
Atorvastatin	P-gp, OATP1B1	CYP3A4	<2
Fluvastatin	OATP1B3	CYP2C9, CYP3A4/2C8 (minor)	5
Lovastatin	P-gp	Significant CYP3A4	10
Pitavastatin	P-gp, OATP1B1	Primarily glucuronide conjugation CYP2C9, CYP2C8 (minor)	15
Pravastatin	OATP1B1, OATP1B3	No appreciable CYP—CYP3A4 extremely minor pathway	20
Rosuvastatin	OATP1B1, OATP1B3	CYP2C9 (10%)	10
Simvastatin	P-gp, OATP1B1	Significant CYP3A4	13

CYP, cytochrome P450 isoenzyme; OATP, organic anion transporting polypeptide; P-gp, P-glycoprotein.

[a]Efflux transporter, P-gp prevents oral absorption of statins and OATP facilitates hepatic uptake of statins from the blood → drugs that inhibit these transporters may ↑ statin plasma concentrations.

CASE 3-2

QUESTION 1: J.A. is a 69-year-old previously healthy male admitted to the medical intensive care unit (ICU) with lower left lobe pneumonia, and he has developed septic shock. His hospital course for the first 18 days of admission consisted of a worsening bilateral pneumonia characterized by profound hypoxia and acute respiratory distress syndrome (ARDS). J.A. is currently deeply sedated and receiving neuromuscular blockade to manage his ARDS, high peak inspiratory pressures (PIPs), and low oxygen saturation (Sao_2).

Medications:

- Propofol IV infusion and fentanyl IV infusion for sedation and analgesia
- Cisatracurium IV infusion for neuromuscular blockade—goal is to improve oxygenation (Pao_2/FIO_2 ratio)
- Pantoprazole IV for stress ulcer prophylaxis

- Heparin subcutaneous (SC) and pneumatic compression boots for deep venous thrombosis (DVT) prophylaxis
- Hydrocortisone IV for corticosteroid insufficiency in critical illness
- Amikacin IV and imipenem/cilastatin IV for day 5 treatment of a multidrug-resistant organism
- Norepinephrine and vasopressin IV infusions for septic shock secondary to pneumonia
- Ophthalmic ointment to lubricate eye while on prolonged neuromuscular blockade
- Lactated Ringer IV infusion for hypotension secondary to septic shock

Vitals: T 101 °F (38.33 °C), heart rate (HR) 105, respiratory rate (RR) 20, BP 95/60

Laboratory values: arterial blood gas (ABG): pH 7.30/P_{CO_2} 42/P_{O_2} 80/CO_2 19/Sao_2 90% on mechanical ventilation: Assist control RR 20, tidal volume 400 mL, positive end-expiratory pressure (PEEP) 10, F_{IO_2} 50%.

Na^+	138 mEq/L	White blood cell count (WBC)	14,600 × 10^3 µL

J.A.'s train-of-four (TOF) is 0/4. A peripheral nerve stimulator, the TOF, is a clinical tool used to monitor neuromuscular blockade. The TOF Scale includes the following: 0/4 indicates that no twitch elicited, neuromuscular blocker agent occupies 100% of postsynaptic nicotinic receptors, and a 100% blockade, whereas 4/4 indicates that <75% of the postsynaptic nicotinic receptors are blocked. The goal of neuromuscular therapy is to achieve an adequate neuromuscular blockade, a TOF of 1/4 or 2/4 (80%–90% of receptors blocked) or the desired clinical effect (eg, accepting ventilation and not over breathing the ventilator), with the lowest dose of neuromuscular agent necessary.[78,79]

What are J.A.'s risk factors for drug interactions?

There are several risk factors for drug interactions in critically ill patients. Critically ill patients are susceptible to drug interactions as a result of a debilitated condition and/or disease state (eg, changes in physiologic pH and body temperature, electrolyte imbalances, organ failure), as well as the multitude of medications prescribed as treatment. Patients in ICU also have altered pharmacokinetics, placing them at an increased risk for an interaction. These changes include the following:

- Decreased GI absorption of enterally administered medications owing to the following: hypoperfusion from shock, increased stomach pH from PPI and histamine blocker therapy, decreased GI motility, or drug effect on carrier proteins, for example, P-gp
- Decreased SC absorption owing to the following: edema, vasopressor therapy, or disease-induced peripheral vasoconstriction
- Increased volume of distribution (V_d) for hydrophilic medications owing to increased total body water from fluid resuscitation and third spacing
- Altered free drug fraction owing to increased α-acid glycoprotein from systemic inflammation and decreased albumin plasma concentrations
- Half-life ($t_{½}$) and clearance (CL) may be affected from decreased hepatic blood flow, renal or hepatic insufficiency, and induction or inhibition of hepatic enzymes by drugs. Patients without renal insufficiency may exhibit augmented clearance.[80,81]

The mode of mechanical ventilation that is used most commonly today is positive pressure ventilation, whereby air is forced into the lungs to improve gas exchange. The use of mechanical ventilation may also affect drug pharmacokinetics by decreasing cardiac output secondary to reduced preload, which, in turn, may compromise perfusion to the liver and kidneys as well as GFR and urine output.[82] This effect is most pronounced in patients who are hypovolemic.

These hemodynamic changes can result in a decrease of the clearance of several drugs.

J.A. has several risk factors for drug interactions. Many of his risk factors are patient specific, including J.A.'s age, organ dysfunction, and acute medical conditions. Additional risk factors are the extended hospital stay in the ICU and multiple medications. J.A.'s specific risk factors are outlined as follows.

Patient Risk Factors

- Age: 69 years old—altered pharmacokinetics and pharmaco-dynamics
- Renal dysfunction: baseline SCr 1.0 mg/dL and current SCr 1.8 mg/dL—decreased renal clearance
- Mild hepatic dysfunction: AST 105 U/mL and ALT 85 U/mL—decreased metabolism
- Pneumonia: T 101 °F (38.33 °C), WBC 14.6 × 10^3 µL, poly 80%, bands 12%—increased catabolism
- Hypotension (result of shock): BP 95/60 on norepinephrine, vasopressin, and lactated Ringer solution—decreased clearance
- Hyperthermia: T 101 °F (38.33 °C)—increased clearance
- Hypophosphatemia: phosphate 0.9 mg/dL—increased neuromuscular blockade (see discussion Case 3-2, Question 2)
- Norepinephrine and vasopressin infusions: potential for decreased blood delivery to the liver and kidneys
- Mechanical ventilation: decreased cardiac output

Other Risk Factors

- Polypharmacy: risk of adverse drug interaction increases with multiple medications
- Duration of hospital stay: 18 days—susceptible to hospital-acquired conditions and subsequent drug therapy

Case 3-2, Question 2: The medical team is concerned that J.A.'s condition may have worsened; he may have had a neurologic event (eg, stroke) overnight. J.A. is clinically unstable to bring to computed tomography (CT). The team needs J.A. to be alert for purposes of conducting a neurologic examination. To undergo the examination, J.A. must have his neuromuscular blockade discontinued and sedation lightened. One and one-half hours after discontinuation of cisatracurium, J.A. is still not moving (TOF 0/4). The medical team feels cisatracurium's paralytic effect should have worn off by now and is concerned about his prognosis. Why has J.A.'s neuromuscular blockade not worn off?

After reviewing the case, the clinician identifies potential drug–condition/disease and drug–drug pharmacodynamic interactions that may contribute to the prolonged neuromuscular blockade. These interactions are discussed as follows.

Background: The incidence of ICU-acquired weakness (polyneuropathy and myopathy) in patients with ARDS is 34% to 60%. This condition can last for months to years and can severely affect a patient's quality of life.[83] There are several risk factors for ICU-acquired weakness that includes prolonged mechanical ventilation, number of days with dysfunction in two or more organs before wakening, corticosteroids, female sex,[84] toxins (eg, botulism), neuromuscular disease states (eg, Guillain–Barré syndrome), severe electrolyte imbalances, prolonged recovery from neuromuscular blockers, deconditioning, length of vasopressor support, and hyperglycemia, just to name a few.[83,85,86] Neuromuscular blockade alone has been associated with ICU-acquired weakness. However, in a multicenter, double-blind trial, investigators found no statistical difference in ICU-acquired paresis between cisatracurium and placebo groups at day 28 or ICU discharge.[85,87] Prolonged recovery from neuromuscular blockade may occur in patients with organ failure and/or conditions that affect the overall clearance of the neuromuscular blocking agent (eg, decreased metabolism of a parent drug, decreased elimination of the parent drug, and/or the active metabolite). In addition to these, certain disease states, conditions, or drugs that may potentiate a blockade may also lead to an increased recovery time.[85,86]

Drug–Condition/Disease Interactions

PHARMACOKINETICS—DRUG METABOLISM/ELIMINATION

The nondepolarizing agent, cisatracurium, is a benzylisoquinolinium compound. It is one of the 10 isomers of the intermediate-acting neuromuscular blocker, atracurium. It is primarily eliminated by Hofmann degradation; optimal breakdown occurs at physiologic temperature (37 °C or 98.60 °F) and pH (7.40).[79] This process results in therapeutically inactive metabolites, monoquaternary alcohol, monoquaternary acrylate, and laudanosine.[88] Cisatracurium's organ-independent elimination is a benefit for J.A. because he has renal and hepatic insufficiency. However, because cisatracurium is degraded by the Hofmann process, alterations in pH and temperature will affect the elimination of the drug. For example, the neuromuscular blockade effect is prolonged with acidosis, whereas elimination is enhanced with an increase in pH. In addition, hypothermia decreases the elimination of cisatracurium, whereas hyperthermia accelerates it. In patients with ICU, the recovery rate from neuromuscular blockade is reported to range from 45 to 75 minutes after discontinuation of a prolonged cisatracurium infusion.[89–91] Because J.A. has both a fever (101 °F [38.33 °C]) and metabolic acidosis (pH 7.30 and HCO_3^- 19), it is difficult to predict the clearance of the neuromuscular blocker.

PHARMACODYNAMIC INTERACTION

A second condition that may add to J.A.'s prolonged blockade is his low phosphate (phosphate 0.9 mg/dL). Phosphate is a building block of ATP. ATP produces energy via an enzymatic reaction by releasing a phosphate group. This reaction is necessary for physiologic and metabolic functions, including muscle contraction. Therefore, a patient with hypophosphatemia is at risk for a myopathy.[92]

Drug–Drug Interaction

PHARMACODYNAMIC—ADDITIVE EFFECTS OF MEDICATIONS

J.A.'s medications may also have additive effects with cisatracurium. A rare adverse effect of amikacin is neuromuscular blockade. The mechanism of blockade involves inhibiting acetylcholine release by competing with Ca^{2+} at the preganglionic nerve terminal and, to a smaller degree, noncompetitive blocking of the receptor.[93] Corticosteroids (eg, hydrocortisone) may also enhance blockade and increase recovery time. Proposed mechanisms for steroidal ICU-acquired weakness include increased muscle sensitivity to corticosteroids because of the lack of movement and skeletal muscle atrophy from the steroid's catabolic actions. In addition, corticosteroids may cause myopathy by denervation; corticosteroids have been shown to inhibit the nicotinic receptor; when combined with the neuromuscular blocking agent, vecuronium, this inhibition is potentiated.[83,94] It is thought that this interaction is more likely to occur with neuromuscular blockers that have a steroid structural ring, such as the aminosteroids (eg, pancuronium, pipecuronium, vecuronium, and rocuronium). However, there have been case reports of prolonged paralysis with the benzylisoquinoliniums (eg, atracurium, cisatracurium, doxacurium, mivacurium, and d-tubocurarine).[85,86,95]

J.A. may need a longer period than 1½ hours to recover from his paralysis because of the following factors: decreased elimination of cisatracurium as a result of acidosis, hypophosphatemia, and medications (amikacin and hydrocortisone). J.A. should also have his phosphate slowly repleted.

Case 3-2, Question 3: How do you explain the drug interactions affecting the antibiotic efficacy of J.A.'s regimen to the medical team?

After reviewing the case, the clinician identifies potential drug–drug physiochemical interaction, as well as drug–condition and drug–drug pharmacodynamic interactions. The mechanism of action of these interactions is discussed in the subsequent section.

Drug–Drug Interaction

PHYSIOCHEMICAL INACTIVATION

It has been well documented that the coadministration of β-lactam antibiotics with aminoglycoside antibiotics can lead to inactivation of the aminoglycoside. The mechanism involves the amino group of the aminoglycoside antibiotic forming an inactive amide with the β-lactam ring of penicillin antibiotics.[96,97] Because penicillins have wide therapeutic index, this interaction primarily affects the efficacy of the aminoglycoside antibiotic.

This interaction has been shown to occur with the extended-spectrum penicillins (eg, azlocillin, carbenicillin, mezlocillin, ticarcillin, and piperacillin). J.A. is currently on amikacin and imipenem–cilastatin antibiotics for the treatment of a multiresistant organism. According to the literature, amikacin is the aminoglycoside that is least susceptible to this interaction.[97] In addition, no inactivation of amikacin was observed when incubated in cilastatin 120 µg/mL human serum for 48 hours at 98.6 °F (37 °C).[98]

This inactivation increases with contact time and is directly proportional to the concentration of penicillin.[99] The rate of elimination of aminoglycoside and imipenem–cilastatin may be decreased because of J.A.'s renal dysfunction. This would increase the contact time of the medications.

Recommendations for J.A.'s antibiotic therapy include administration of medications separately; serum concentrations of aminoglycosides should be assayed immediately after drawn, or if analysis is delayed, either add penicillinase to the blood sample or freeze at −158 °F (−70 °C); and because of his renal dysfunction, close monitoring of aminoglycoside serum concentrations is indicated.[99,100]

Drug–Condition/Disease Interaction

PHARMACODYNAMIC INTERACTION

The pharmacodynamic actions of amikacin may be decreased because J.A. is acidotic.

Amikacin enters the bacterial cell and reaches its site of action in three stages: ionic binding, energy-dependent phase I (EDP-I), and energy-dependent phase II (EDP-II) transport or uptake.

Ionic Binding to the Outer Membrane: At physiologic pH, amikacin (pK_a 8.1) is a highly ionized basic cation. It binds to anionic lipopolysaccharides (LPSs), polar heads of phospholipids, and proteins on the outer cell membrane of gram-negative bacteria and phospholipids and teichoic acids of Gram-positive bacteria.[101] This leads to displacement of cell wall Mg^{2+} and Ca^{2+} bridges that link LPS, resulting in the formation of pores in the cell wall where amikacin can enter into the periplasmic space.[102]

EDP-I: Amikacin is transported across the cytoplasmic membrane. EDP-I is dependent on pH and oxygen. Amikacin activity will decline in low pH and anaerobic conditions (eg, abscesses).[102]

EDP-II: Amikacin is transported to the site of action, binding to the ribosomes.[102]

Drug–Drug Interaction

PHARMACODYNAMIC—ADDITIVE/SYNERGISTIC EFFECT OF MEDICATIONS

Penicillins form a covalent bond with the enzymes, the penicillin-binding proteins (PBPs) (specifically transpeptidase, endopeptidase, and carboxypeptidase), inhibiting their action. These enzymes are needed for the final step of bacterial cell wall synthesis, the cross-linking between peptide side chains on the polysaccharide backbones of the peptidoglycan.[103] Cell wall inhibitors such as penicillins and vancomycin may expedite aminoglycoside entry into the bacterial cell, resulting in synergistic effects when treating some organisms.[102]

J.A. is critically ill with renal failure, ARDS, pneumonia caused by a multiresistant organism, septic shock, and a metabolic acidosis. It is important to closely monitor his aminoglycoside therapy for efficacy (peaks) and toxicity (troughs).

This case illustrates the difficulties surrounding drug interaction identification, assessment, and follow-up intervention. Clinicians must recognize that literature to support the presence of a drug interaction is often scant and not always definitive and that the optimal intervention may rely on clinical judgment. Refer to Chapter 56, Care of the Critically Ill Adult.

CASE 3-3

Question 1: D.T. is a 67-year-old male who began taking imatinib about 10 years ago to treat a rare sarcoma: partially resected gastrointestinal stromal tumor (GIST). D.T. currently takes 600-mg imatinib daily, as well as rabeprazole and furosemide. He states that he is currently not taking any nonprescription medications. He continues to go to the cancer treatment center for continued monitoring. He contacts the cancer clinic to let them know that in 4 weeks he will be traveling to Africa to go on a safari. He mentioned that the friends whom he will be traveling with told him that he will need malaria prophylaxis.

Are there are any potential drug interactions, and which antimalarial agent would be an appropriate selection?

Imatinib mesylate belongs to a class of drugs known as selective tyrosine kinase inhibitors (TKIs).[104] It inhibits the BCR-ABL tyrosine kinase, the constitutive abnormal tyrosine kinase created by the Philadelphia chromosome abnormality in chronic myeloid proteins.[97] It also inhibits the tyrosine kinase for platelet-derived growth factor (PDGF) and c-kit. TKIs, such as imatinib, are extensively metabolized via CYP enzymes (with a large degree of interindividual variability).[105] Imatinib is metabolized primarily by CYP3A4, whereas CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A5 are reported to have a minor role in its metabolism.[106] In addition, imatinib is a substrate of human organic cation transporter type 1 (hOCT1), P-gp, and BCRP, though it is unclear whether imatinib is a substrate or an inhibitor of Breast Cancer Resistance Protein (BCRP).[107–110] Imatinib also competitively inhibits the metabolism of drugs that are CYP2C9, CYP2C19, CYP2D6, and CYP3A4 substrates.[111] It is also highly protein bound, with ~95% bound to human plasma proteins.[106,112–114]

Drug–Drug Interaction

PHARMACOKINETICS—DRUG METABOLISM/ELIMINATION

There are several considerations of potential drug interactions with imatinib. Drug interactions should be considered when imatinib is administrated with other agents in the CYP3A family.[104] In particular, interactions are likely with inhibitors of CYP3A4, such as voriconazole or amiodarone, resulting in increases in the plasma concentration of imatinib. Concomitant use of rifampicin or other strong CYP3A4 inducers with imatinib should be avoided. In addition, concomitant administration of imatinib with agents that are both inhibitors of CYP3A4 and P-gp increases plasma and intracellular imatinib concentrations. Examples of dual CYP3A4 and P-gp inhibitors include verapamil, erythromycin, clarithromycin, ketoconazole, fluconazole, and itraconazole.[107,115,116] TKIs, such as imatinib, also can inhibit drug transporters and enzymes, resulting in changes in the exposure of coadministered drugs. St. John's wort significantly altered the pharmacokinetic profile of imatinib, with reductions of 30% in the medium area under the concentration–time curve (AUC). Patients should be cautioned regarding the concomitant use of products, such as St. John's wort, as well as other inducers, that may necessitate an increase in imatinib dosing to maintain therapeutic efficacy.[117,118] Drug interactions involving protein binding of imatinib and other highly protein-bound drugs are not well understood.[104]

A study published in 2016 examined DDIs observed in patients treated with imatinib.[119] The investigators performed two observational studies to identify the medications that were most frequently dispensed simultaneously with imatinib through the French health insurance reimbursement database SNIIRAM (Systeme National d'Information Inter-Regimes Assurance Maladie) as well as the ADRs related to DDIs involving imatinib using the French Pharmacovigilance Database. A sample of 544 patients from SNIIRAM with at least one reimbursement for imatinib were identified between January 2012 and August 2015. Of this cohort of 544 patients, 89.3% (486) of patients had at least one prescription

medication that could potentially interact with imatinib based on mechanism of action (eg, metabolism pathways). The results of the study also found that the most frequent DDI was with paracetamol (acetaminophen; 77.4%), which resulted in an increased risk of paracetamol toxicity. Other study findings with >10% of patients with potential DDIs were with PPIs (33.3% for omeprazole) or dexamethasone (23.7%) that could reduce imatinib's effectiveness and with levothyroxine (18.5%) that could decrease levothyroxine's effectiveness. The suspected mechanisms of this drug interaction with levothyroxine are an induction by imatinib of nondeiodination clearance or induction by imatinib of uridine diphosphate glucuronyl transferases.[120,121] Study results also found that the most frequently used drugs that could increase imatinib toxicity were ketoconazole and clarithromycin (5.1% and 4.7%, respectively).[119] The overall findings of this study suggest that at least 40% of patients who are receiving imatinib are at risk of DDIs and may reach an even higher rate according to the results of the study performed in SNIIRAM. The highest rate of potential DDIs in this study with imatinib was with the following agents: paracetamol, PPIs, dexamethasone, or levothyroxine. Based on the study findings, the investigators provided recommendations regarding the use of imatinib with specific agents. It is recommended that the reader refers to the package insert of imatinib for drug interactions and dosing guidelines. Further study regarding DDIs with imatinib, as well as other TKIs, is warranted.

With regard to selection of an antimalarial agent for D.T., chloroquine, mefloquine, and atovaquone-proguanil (Malarone®) may have potential interactions with imatinib. The proguanil component is metabolized via the CYP2C19 pathway. Given the options that can be used for malaria prophylaxis in D.T., doxycycline would be an appropriate antimalarial agent used for malaria prophylaxis that does not interact with imatinib or D.T.'s other medications (refer to Chapter 81, Parasitic Infections, for malaria prophylaxis options). The most commonly reported adverse effects with doxycycline are GI effects, including nausea, vomiting, abdominal pain, and diarrhea. Esophageal ulceration associated with doxycycline is a rare but well-

described adverse event. D.T. should be counseled to take doxycycline with food and plentiful fluids, in an upright position in order to minimize GI adverse effects. Because doxycycline can cause photosensitivity and D.T. will be on a safari, the risk of photosensitivity can be reduced by the use of an appropriate sunscreen and wearing protective clothing, including a hat. D.T. should also be counseled regarding the use of paracetamol (acetaminophen) and also to check in advance with his pharmacist before taking any natural products that may be metabolized via CYP.

RESOURCES AND EVIDENCE FOR CLINICAL DECISION SUPPORT

Health care providers have become increasingly challenged on devising optimal approaches to managing drug interactions. Patient safety initiatives have expanded in efforts to improve the health care delivery system with medication error prevention as a high-priority area. The consensus recommendations published by the expert group in 2015 have provided a road map for addressing the key concerns to improve the approach to evaluating DDI evidence for clinical decision-making.[5] As part of this process, it was important to review existing methods for evaluating DDIs. The Drug Interaction Probability Scale (DIPS), a 10-item scale, was developed to evaluate individual case reports for DDIs by assessing an adverse event for causality by a DDI.[122] This tool was developed to address limitations of previous assessment instruments, such as the Naranjo scale. The reader is referred to Appendix C of the consensus recommendations for further information regarding DIPS and other available instruments.[5] The expert group also discussed the current systematic approaches using clinical decision support (CDS) systems, their limitations, and the need for a new assessment instrument to objectively evaluate a body of evidence to establish the existence of a DDI. One of the key challenges of CDS systems is to

determine what evidence is required for a DDI to be applicable to an entire drug class. Pharmacokinetic interactions are rarely generalizable to all agents within a drug class, and if there is class effect, the magnitude of the effect can often vary, which typically necessitates that each drug is reviewed individually. In some cases, pharmacokinetic interaction data may be extrapolated from one agent to other agents in the small class if the purported mechanism of interaction involves common pharmacologic effects.

To advance this important initiative, recently, another group of experts convened to address the following: (a) to outline the process to use for developing and maintain a standard set of DDIs, (b) to determine the information that should be included in a knowledge base of standard DDIs, (c) to determine whether a list of contraindicated drug pairs can or should be established, and (d) to determine how to more intelligently filter DDI alerts.[123] Their recommendations for selecting DDIs for CDS were released in 2016. The reader is referred to both the 2015 and the 2016 recommendations.[5,123]

Because various avenues are examined to reduce the risk of drug interactions within society, it is essential as health care providers that we improve patient education regarding medication information. This strategy includes our communications with patients both verbal instructions and patient instruction leaflets given with the prescription. It is important to consider translation of information into different languages and to also promote culturally competent communication within every health care setting. The use of auxiliary warning labels placed on the medication package, books, and referring patients to quality health information on the Internet. Pharmacists are uniquely positioned to provide important information regarding OTC medications, including herbal products when patients receive prescription information, and when they are seeking recommendations for OTC products.[124]

CONCLUSION

Given the complexities of data on drug interactions and the complexities within the health care systems, health care providers have become increasingly challenged on devising optimal approaches to managing drug interactions.[3] Patient safety initiatives have expanded in efforts to improve the health care delivery system with medication error prevention as a high-priority area. Medication errors may be related to professional practice, health care products, procedures, and systems, including prescribing, order communication, product labeling, packaging, nomenclature, compounding, dispensing, distribution, administration, education, monitoring, and use.[2,4] Because exposure to DDIs is a significant source of preventable drug-related harm, appropriate medication use, including drug interaction management, will avoid medication errors.[5]

Although the majority of drug interactions are clinically insignificant, in certain circumstances, drug interactions are considered to be highly significant and can cause harm. Patients should be informed of the importance of maintaining a complete medication profile, including OTC medications, herbs, and dietary supplements. The incorporation of pharmacogenetic information into risk assessment of patients will improve our ability to prevent DDIs and to better evaluate interactions with biologic drugs.

More well-controlled studies are needed after drug approvals. Population-based studies are useful to determine the severity of, incidence of, and clinical importance of drug interactions. Pharmacogenetic research can further improve the precision of DDI evidence and CDS by identifying patient-specific predisposing factors. Future directives will identify the most appropriate process to rate the quality of DDI evidence and provided graded recommendations to reduce the risk of adverse consequences.[5]

Pharmacogenomics and Personalized Medicine

Hyun Kim, Shannon F. Manzi, Laura Chadwick, and Jonathan Picker

CORE PRINCIPLES		CHAPTER CASES
1	Pharmacogenomics is an important component of the broader concept of personalized medicine, which incorporates a variety of factors, both genetic and nongenetic, to guide targeted and individualized therapeutic decisions.	**Case 4-1 (Question 1), Figure 4-1, Tables 4-1, 4-2**
2	Pharmacogenomic effects can be both pharmacokinetic and pharmacodynamic in nature. Pharmacokinetic effects are observed when variants affect the absorption, distribution, metabolism, or excretion of a drug. Pharmacodynamic polymorphisms may result in variable amounts of drug target enzymes or	**Case 4-2 (Questions 1, 2)**

	receptors, as well as possible changes in the drug target shape. These variations may render therapy ineffective or necessitate dose changes in certain affected populations.	
3	DNA polymorphisms affecting drug metabolizing enzymes can result in gain of function, loss of function, or have no effect on function of the enzyme produced. In some cases, significant toxicity can result.	**Case 4-3 (Question 1), Figure 4-2, Table 4-3** **Case 4-4 (Question 1), Table 4-4**
4	Drug transport proteins and binding targets can also be affected by pharmacogenomic variants.	**Case 4-5 (Questions 1, 2), Table 4-5**
5	Human leukocyte antigen (*HLA*) genes are unique in that the presence of a variant does not impact the metabolism of a drug, but instead may indicate the likelihood of the development of a life-threatening reaction.	**Case 4-6 (Questions 1–3), Table 4-6**
6	Test interpretation is crucial to the practical application of pharmacogenomic data. In particular, cytochrome P450 (CYP) 2D6 is a well-described CYP enzyme responsible for ~25% of all drug metabolism. However, *CYP2D6* is a complicated gene locus subject to multiple variants, pseudogene interference, and copy number variation, making interpretation difficult.	**Case 4-7 (Questions 1, 2), Table 4-7** **Case 4-8 (Question 1)**
7	Age-based development adds a level of complexity when assessing	**Case 4-9 (Question 1), Figure 4-3**

	pharmacogenomic markers in pediatric patients. Many of the pharmacogenomic dosing guidelines have not been validated in infants and children.	
8	Implementation of pharmacogenomics into practice is increasing but continues to face many challenges, including the appropriate determination of when and whom to test; storage, analysis, and security of genetic data; and considerations for using pharmacogenomic data and recommendations in practice.	**Case 4-10 (Question 1)** **Case 4-11 (Questions 1, 2)**

INTRODUCTION

Pharmacogenomics is the study and application of gene expression on drug pharmacokinetics and pharmacodynamics. This term is often used interchangeably with "pharmacogenetics." By strict definition, pharmacogenetics is used in the context of a single gene's influence on a drug, whereas pharmacogenomics refers to the broader study of the full genomic impact on drug behavior.[1] Because genetic variants are specific to the individual, the use of pharmacogenomics in clinical practice has become a core component of the personalized medicine and precision medicine movements.[2,3]

The study of pharmacogenomics is not new because there are cases in the literature from the 1950s and 1960s describing the influence of a person's genetics on drug toxicity.[4,5] The first recognition of individual differences in response to consumption of a product was favism, a form of hemolytic anemia described by the ancient Greek physicians before the third century BC.[6] They

recognized that in some people the consumption of fava beans had potentially severe consequences. Whether this was the source for Pythagoras' famous abhorrence of the beans, however, remains uncertain. More recently, with the advent of newer, cheaper, faster DNA sequencing techniques, the study of pharmacogenomics has exploded. We are now able to begin transitioning pharmacogenomic knowledge from the research realm to the clinic, although not without challenges.

A brief review of the basics of human genetics in the context of pharmacogenomics is discussed here. Students are encouraged to utilize the selected references at the end of the chapter for further review. Although somatic tumor genetics and the study of mutations found in cancer cells are becoming increasingly important when selecting antineoplastic drugs, this chapter primarily focuses on germline mutations in human DNA that affect drug absorption, distribution, metabolism, and excretion.

Genes code for proteins, such as enzymes, structural components of cells, hormones, antibodies, and transport molecules. In pharmacogenomics, the gene and the enzyme often share the same name. For example, the gene that codes for cytochrome P450 CYP3A4 is known as *CYP3A4* and the gene that codes for thiopurine methyltransferase (TPMT) is known as *TPMT*.

The human genome is made up of 3 billion nucleotide base pairs arranged on 23 pairs of chromosomes. Nucleotides include adenine (A), guanine (G), cytosine (C), and thymine (T), with variants in nucleotide sequences contributing to each individual's unique physiologic characteristics, traits, and features, such as hair color, eye color, height, risk of disease, and ability to process medication.

In most, but not all, cases, two copies of each gene are present: one inherited from your mother and one from your father. Each copy of a gene is referred to as an *allele*. If both the maternal and paternal alleles are the same, then the individual is considered homozygous for that gene. If the parental copies differ, then the patient is considered to be heterozygous for that gene. Nucleotide changes that differ from the most commonly observed sequence are referred to as *variants*. Although the formal variant definition states that the

observed change occurs in at least 1% of the population, the term is often used in practice regardless of population frequency.

A change in a single base pair is termed a *single-nucleotide polymorphism*, or SNP (pronounced “snip”) (**Fig. 4-1**). SNP locations are mapped and named using a reference SNP cluster ID, or rsID, discussed in more detail in Case 4-5. An SNP that adversely changes the function of the protein encoded for by a gene is called a *pathogenic variant* or, historically and colloquially, a *mutation*. Many of the pharmacogenetic variants discussed in this chapter are SNPs. SNPs are responsible for 90% of pharmacogenetic variability and can result in gain of function with greater production of the associated enzyme and higher than normal enzymatic activity, or loss of function with reduced or no enzyme production and decreased enzymatic activity. Other variant types include nucleotide insertions or deletions, commonly referred to as *indels*. In many cases, indels terminate protein production as a result of frameshift changes that alter the translation of amino acids.

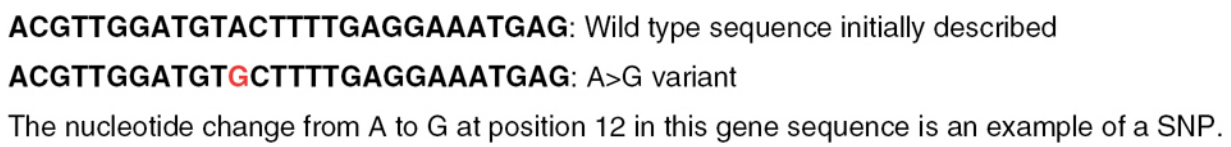

Figure 4-1 Example of a single-nucleotide polymorphism (SNP).

In classical Mendelian genetics, most inheritance of disorders occurs in either a dominant or recessive manner. For dominant disorders, a change in a single allele is sufficient to elicit an undesired physiologic effect. These changes can be passed down from one generation to the next or occur as new, or de novo, mutations within an individual for the first time. With recessive disorders, a person must inherit two defective copies of a gene for there to be a functional consequence. Parents who are heterozygous for a gene associated with a recessive disorder are usually unaffected by the disorder and are termed *carriers*. When both parents are carriers, one in four of their offspring is at risk for inheriting the disorder even with no family history of the disease.

Unlike the discrete pattern of dominant and recessive disorder inheritance, pharmacogenes, or genes associated with drug action and kinetics, tend to operate on more of a continuum. Variants within pharmacogenes often result in a spectrum of effects, ranging from mild to more pronounced, depending on the number of functional alleles present. Pharmacogenetic variants are also typically "silent" in the absence of relevant drug exposure, making family history a somewhat less reliable tool.

The nucleotides, including any variants if present, make up alleles that determine a person's genotype for a given gene. The term *phenotype* refers to the expression, or physical manifestation, of a genotype. In some cases, a phenotype is visibly obvious, such as skin color, eye color, or hair color. In other cases, it is measurable, such as is the case for a person's blood type or the amount of a CYP450 metabolizing enzyme they generate. In the context of pharmacogenomics and metabolizing enzymes, patients are often classified as having a phenotype of ultrarapid metabolizers, extensive metabolizers, intermediate metabolizers, or poor metabolizers based on their genotype.[7] There are several other relevant phenotypes relating to pharmacogenomics that are discussed in this chapter, particularly those that deal with drug targets or pharmacodynamic responses.

The complexity of most drug metabolism pathways can make applying phenotypes to clinical drug dosing decisions complex. It is rare for a pathway to involve a single enzyme resulting in one inactive metabolite that is immediately excreted by the body. Instead, most drugs utilize multiple metabolizing enzyme pathways, rely on several drug transporters, and have many metabolites of varying activity. Each of these pathways may be subject to variable gene expression, coupled with indirect genetic and environmental effects on other characteristics such as disease, weight, nutrition, and age. With the spectrum of factors to consider, using pharmacogenomic interpretations in a clinical setting can be extremely complicated.

For common pharmacogenes, the representation of a person's genotype is often noted by a "*," known as a *star allele*. For example, a normal or "wild-type" allele status is often denoted as **1/*1*.[8] As

other alleles are discovered, they are numbered sequentially as *2, *3, and so on. Because discoveries are inevitably sometimes reported simultaneously from different sources, there is occasionally an overlap of star alleles and the variants represented. There are several worldwide databases for reporting new pharmacogenomic variants, including the Human Cytochrome P450 (CYP) Allele Nomenclature Database, http://www.cypalleles.ki.se/, and the Database of Genomic Variants, http://dgv.tcag.ca/dgv/app/home.

During drug development and postmarketing analyses, it often becomes clear that some patients either have severe adverse drug reactions (ADRs) or do not respond to the population-derived standard dose. Adverse drug reactions (ADRs) are defined as *unintended outcomes occurring in the absence of medication error or lack of proper adherence to the drug*, and are costly.[9,10] The 2000 Institute of Medicine (IOM) "To Err Is Human" report cited over 2 million reported ADRs in the United States per year resulting in ~100,000 deaths and at a cost of $29 billion annually.[11] It is estimated that 87.7% of outer quadrant adults are taking at least one prescription drug, 35.8% are taking more than five prescription drugs, 37.9% use over-the-counter medications, and 63.7% use dietary supplements.[12] It is well known that ADRs often go unnoticed and even more frequently unreported, making the actual numbers likely far higher.

The clinical application of pharmacogenomics has allowed us to not only explain some of these historical reactions but also helps clinicians predict who may be at higher risk for developing an adverse reaction if exposed to a drug or drug class.[13] With this understanding, clinical decisions can be made to lower a person's risk of adverse reactions. Given that >90% of individuals carry at least one potential clinically significant pharmacogene genotype, overall risk in the pharmacogenetic space is not insignificant.[14] Avoidance of ADRs has a measurable impact on a patient's quality of life, decreases overall health care costs, and lessens the time burden on health care providers managing the adverse reactions. However, acceptance of clinical pharmacogenomic testing is not

universal and there remains the challenge of conclusively validating the genetic variant association with the adverse reaction.[15]

Guidelines for drug dosing and selection have been developed by the Clinical Pharmacogenomics Implementation Consortium (CPIC, pronounced “See-Pick”) and the Pharmacogenetics Working Groups of the Royal Dutch Pharmacists Association (DPWG). Each guideline is rated on the level of evidence available to support the recommendation.[16] Currently, there are 26 CPIC Level I Evidence published guidelines available on www.pharmgkb.org, a website supported by the National Institutes of Health (NIH) and hosted by Stanford University.[17] The site houses a wealth of information, including pathway diagrams, annotated bibliographies, and look-up tables. Importantly, the guidelines do not address who should be tested but instead focus on what to do with the data if available.

PHARMACOKINETIC IMPLICATIONS

CASE 4-1

QUESTION 1: A.S. is a 2-year-old female diagnosed with active multidrug resistant tuberculosis (MDR TB). The Centers for Disease Control and Prevention (CDC) treatment protocol recommends isoniazid, rifampin, ethambutol, and pyrazinamide for initial therapy. Her mother is concerned because several family members in their home country of China had developed serious “liver problems” when they took isoniazid, and she insists on the “gene test” for A.S.

What genetic testing is A.S.’s mother referring to and what are the risks of toxicity in relation to isoniazid therapy?

Isoniazid is part of the four-drug regimen used to treat both active and latent tuberculosis (TB) infection because it is bactericidal against *Mycobacterium tuberculosis* organisms.[18] One of the most commonly reported side effects, sometimes leading to premature discontinuation of the drug, is drug-induced liver injury (DILI).

The metabolism of isoniazid is complex, with the *N*-acetyltransferase-2 (NAT2) enzyme playing a key role in the pathway.[19] In the metabolism of isoniazid, NAT2 acetylates both the parent drug and a hydrazine metabolite, converting the hydrazine metabolite to acetyl hydrazine (AcHz).[20] The AcHz metabolite is believed to be the main cause of the liver injury observed with isoniazid therapy.

The NAT2 enzyme is generated from a gene of the same name, with several known polymorphisms leading to alleles associated with either slow or rapid acetylation rates. Individuals homozygous for slow alleles are considered "slow acetylators," those homozygous for rapid alleles "rapid acetylators," and heterozygotes deemed "intermediate acetylators" (**Table 4-1**). When NAT2 acetylation rates are reduced, it allows for a buildup of AcHz; therefore, DILI has been found to be highest in patients who are slow acetylators.[21] In addition to isoniazid, NAT2 is also a known acetylator of drugs and/or metabolites in other drug pathways, although the clinical effects of *NAT2* genotype on these drugs are less studied: sulfonamides (sulfamethoxazole, metabolites of sulfasalazine); and aromatic and aliphatic amines (procainamide, dapsone, metabolite of clonazepam, mescaline).[22]

Table 4-1
***NAT2* Genotypes and Phenotypes**

***NAT2* Allele Activity**		
Slow	**5–7, *10, *12D, *14, *17, *19*	
Rapid	**4* (wild type), **11, *12A–C, *13, *18*	
NAT2 Phenotype Summary		
Genotype	**Acetylator Rate**	**Clinical Manifestation With Isoniazid Therapy**
Homozygous slow	Slow	Increased risk of adverse drug events
Heterozygous	Intermediate	No increased risk of adverse drug events or treatment failure related to genotype
Homozygous	Fast/rapid	Possible increased risk of treatment failure

rapid		

The “gene test” mentioned by A.S.’s mother is a test for the *NAT2* gene. A variety of pharmacogenomic tests are available to examine SNPs in the *NAT2* gene and assign a patient’s genotype, either from a targeted assay or as part of a more extensive gene panel. Preemptive *NAT2* testing before isoniazid therapy is not currently the standard of care; however, evidence suggests that this practice may be beneficial in some populations with a high prevalence of DILI in slow acetylators.[23–28] Asian cohorts have been found to have the highest rates of DILI in the setting of a slow acetylator status (see summary of studies in **Table 4-2**). Although there are no formal dosing guidelines set for isoniazid therapy in the context of genotype or acetylator status, a study completed by Azuma et al with 155 Japanese patients with TB proposed a modified, genotype-based dosing regimen with successful outcomes that were both clinically and statistically significant (results summarized in **Table 4-3**).[29]

Table 4-2
Summary of *NAT2* Genotypes and Hepatotoxicity Risk With Isoniazid Studies

Study	Study Type	Population	Metric	Result
Sun et al[24]	Meta-analysis *N* = 5 case–control studies 133 cases (hepatotoxicity) 492 controls	Chinese Japanese East Indian Caucasian	Prevalence of SA status in hepatotoxicity cases vs control	*Overall*: no significant finding *Asian subgroup analysis*: ↑ risk hepatotoxicity for SAs OR 2.52 (CI: 1.5–4.3)
Wang et al[25]	Meta-analysis *N* = 14 case–control studies 11 Asian, 3 non-Asian 474 cases (hepatotoxicity) 1446 controls	Japan China Taiwan India Korea Turkey Switzerland USA (8%)	SA hepatotoxicity risk vs RA	↑ risk hepatotoxicity for SAs OR_Asian: 4.9 (CI: 3.3–7.1) OR_non-Asian: 3.7 (CI 1.3–10.5) ↑ risk hepatotoxicity in combination regimen
Ben Mahmoud et al[26]	Observational case–control *N* = 65	Tunisian	SA hepatotoxicity risk vs RA and IAs	↑ risk hepatotoxicity for SAs OR 4.3; CI: 1.5–18
Du et al[27]	Meta-analysis *N* = 26 studies 1198 cases 2921 controls	Asian Caucasian Middle Eastern Brazilian	Prevalence of SA status in hepatotoxicity cases vs control	*Overall*: ↑ risk hepatotoxicity for SAs OR 3.1 (CI: 2.5–3.9) *Caucasian*: no significant finding
Huang et al[28]	Observational case–control *N* = 224	Taiwan	SA hepatotoxicity risk vs RA	↑ risk hepatotoxicity for SAs OR 2.8 (CI: 1.3–6.2)
Pasipanodya et al[23]	Meta-analysis *N* = 3471	United Kingdom Asia East Africa United States Prague	RA treatment failure risk vs SA	↑ risk of treatment failure for RAs RR 2 (CI: 1.5–2.7)

CI, confidence interval; IA, intermediate acetylator; OR, odds ratio; RA, rapid acetylator; RR, risk ratio; SA, slow acetylator.

NAT2 genotype guided regimen reduces isoniazid-induced liver injury and early treatment failure in the 6-month four-drug standard treatment of tuberculosis: a randomized controlled trial for pharmacogenetics-based therapy. *Eur J Clin Pharmacol*. 2013;69(5):1091–1101. doi:10.1007/s00228-012-1429-9.

Several questions remain as to how to most safely and appropriately incorporate *NAT2* genotype results into a widespread clinical application. For example, pediatric patients such as A.S. offer a unique set of challenges because recommended isoniazid starting doses are within a higher range (10–15 vs 5 mg/kg for adults), and dose modifications based on genotype have not been studied in this population. Genotype concordance with predicted phenotype has also been found to be lower in pediatric patients.[30] In addition, ethnic variation among study results also suggests that testing may be more beneficial in certain groups, namely, those with Asian ancestry. As is the case when using ethnicity to determine whether to complete any genetic test, self-reported ancestry is not always a reliable means of predicting someone's actual genetic lineage. With a foundation of promising preliminary studies, a continued focus on the *NAT2* genotype effects on isoniazid safety has the potential to result in institutions and organizations adopting policies to proactively test *NAT2* in the context of isoniazid treatment to both prevent adverse drug events and increase treatment success.

PHARMACODYNAMIC IMPLICATIONS

CASE 4-2

QUESTION 1: E.F. is a 51-year-old male status post ST-elevation myocardial infarction (STEMI) and atrial fibrillation with a residual left ventricular thrombus. Despite aggressive dose escalations of warfarin, his international normalized ratio (INR) will not budge above 1.7. His current dose of warfarin is 10 mg daily and he reports no dietary changes or excessive vitamin K intake. There are no drug–drug interactions identified in his regimen. The cardiology team asks about pharmacogenomic testing.

What is known about the genes involved in warfarin response that would impact E.F.'s INR?

Warfarin works by inhibiting vitamin K epoxide reductase complex subunit 1 (VKORC1), a key enzymatic component in the vitamin K clotting pathway.[31] By inhibiting VKORC1, synthesis of vitamin K–dependent clotting factors II, VII, IX, and X is reduced, and anticoagulation is achieved under conditions where thrombosis is a concern, such as atrial fibrillation. The amount of VKORC1 present in a person is linked to the *VKORC1* gene, a key pharmacodynamic consideration. Patients with the GG genotype at *VKORC1* rs9923231 are considered warfarin insensitive, meaning they are likely to require larger doses of warfarin to effectively inhibit the VKORC1 pathway. The AA genotype has been associated with lesser amounts of VKORC1, and therefore these patients are warfarin sensitive and require lower doses of warfarin for inhibition and anticoagulation.[32]

Another significant factor affecting warfarin dosing and response is the effect of genetic variants on warfarin metabolism. Warfarin is taken orally as a racemic mixture of R- and S-enantiomers, and its subsequent metabolism is complex, involving multiple genes and pathways. The primary pathway of the S-enantiomer, the more active form of the drug, is via the CYP2C9 enzyme.[32] CYP2C9 is the predominant enzyme pathway responsible for >25% of the variation in warfarin metabolism. *CYP2C9* is highly polymorphic, with several known variants within the population linked to reduced metabolic rates, including the *CYP2C9 *2* and *3* alleles. Reduced warfarin metabolism leads to increased concentrations of the active form of

the drug. These patients may require lower warfarin doses, and thus may be at increased risk for bleeding using standard dosing algorithms.[32]

A more recent gene of focus with limited evidence relating to warfarin sensitivity is *CYP4F2*.[33] *CYP4F2* affects the metabolism and, therefore, the physiologic levels of vitamin K. Patients with the TT genotype for *CYP4F2* rs2108622 are thought to maintain higher concentrations of vitamin K, and therefore require ~1 mg more warfarin per day than do patients with the CC genotype. Although current dosing models focus strictly on *CYP2C9* and *VKORC1* genotypes for warfarin initiation, *CYP4F2* has shown early promise as a potential factor for strengthening the effectiveness of dose prediction algorithms in some ethnicities.[34]

It is important to remember that many nongenetic factors such as age, weight, diet, smoking status, medication interactions, and others contribute to great variability in warfarin dosing within patient populations. Drug–drug interactions in which the CYP2C9 enzyme may be induced or inhibited can affect both the rate of warfarin metabolism and the pharmacogenomic phenotype, a phenomenon termed *phenoconversion*. In addition, a diet high in vitamin K will make warfarin less effective because this facilitates increased synthesis of vitamin K–dependent clotting factors. Algorithms for determining appropriate starting doses for patients older than age 18 years based on both nongenetic and genetic factors are available at www.warfarindosing.org. Close monitoring of INR is also recommended to ensure proper anticoagulation and reduced risk of bleeding.

CASE 4-2, QUESTION 2: What other drugs are significantly affected by the CYP2C9 pathway?

CYP2C9 is estimated to play a role in the metabolism of up to 20% of commonly used medications.[35] From these medications, several associations have been found linking variants in the CYP2C9 pathway to both increased rates of adverse drug events and variable

medication response. Examples of such drugs include phenytoin, certain nonsteroidal anti-inflammatory drugs (NSAIDs, such as celecoxib and diclofenac), sulfonylureas, losartan, and certain statins (such as fluvastatin and simvastatin). Patients with *2 or *3 alleles may be at increased risk for toxicities at standard doses of drugs that are processed through the CYP2C9 pathway because of decreased metabolism and increased parent drug concentrations and may require reduced dosing or increased monitoring.

IMPLICATIONS IN ACUTE TOXICITY

Many known variants within the genes that code for enzyme proteins exist, possibly affecting the rate at which the enzyme is able to metabolize drugs through its pathway. These variants may result in either reduced enzyme function, leading to increased concentration of the parent drug, or increased enzyme activity with decreased concentrations of a parent drug. The clinical effects of variants depend on whether the parent drug is pharmacologically active or a prodrug.

CASE 4-3

QUESTION 1: T.B. is a 10-year-old male admitted for status epilepticus, treated with intravenous (IV) lorazepam and IV fosphenytoin on presentation, aborting the seizures. His past medical history is significant for congenital hydrocephalus, a ventriculoperitoneal (VP) shunt, and refractory epilepsy secondary to an in utero right middle cerebral artery (MCA) stroke. On day 5 of his hospitalization, he is still extremely lethargic, and his free phenytoin level is high, peaking at 3 µg/mL on day 2 and 1.4 µg/mL on day 5. Looking at his records, he received the initial loading dose of IV fosphenytoin 500 mg phenytoin sodium equivalents (PE) (18 mg PE/kg) followed by a single maintenance dose of IV fosphenytoin 140 mg PE (5 mg PE/kg) 5 hours later on day 1 of the hospitalization (**Fig. 4-2**). He has no clinically relevant drug–drug interactions, and his albumin is normal.

What is a possible reason for the toxicity T.B. is experiencing?

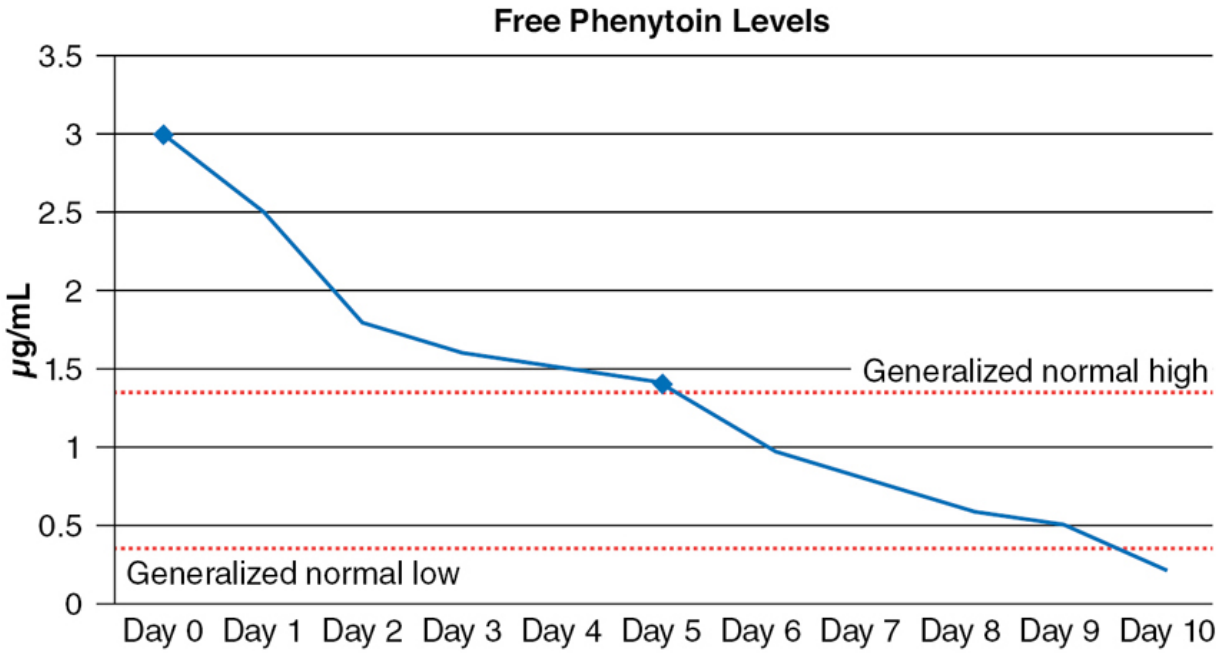

Figure 4-2 Free phenytoin levels (Case 4-3).

Phenytoin/fosphenytoin serum concentrations can be difficult to control and are complicated by multiple factors including Michaelis–Menten kinetics or capacity-limited metabolism. Drugs that follow Michaelis–Menten kinetics go from first to zero order, meaning that metabolism increases with increasing concentration until enzyme saturation takes place.[36] Once saturation is reached, drug plasma concentrations can increase to toxic levels in a fast and unpredictable manner. In addition, many factors affect an individual's safe and effective phenytoin dose, including albumin levels, other medications in the patient's regimen, and pharmacogenetics.

Phenytoin has many chronic effects associated with long-term use including hepatotoxicity, osteoporosis, megaloblastic anemia, gingival hyperplasia, hirsutism, and peripheral neuropathy.[37] In the acute setting of toxic plasma concentrations or an overdose, phenytoin toxicity can manifest with a variety of signs and symptoms, including central nervous system (CNS) effects (dizziness, confusion, drowsiness, and ataxia) as well as gastrointestinal (GI) upset and nausea. Phenytoin is also associated with severe cutaneous reactions such as Stevens–Johnson syndrome (SJS) and toxic epidermal necrosis (TEN), discussed in Case 4-6.

Fosphenytoin is a prodrug that is converted by plasma esterases to the active drug phenytoin. Phenytoin is further metabolized by CYP2C9 to phenytoin arene oxide, which is then broken down to multiple metabolites that are eventually excreted.[38,39] The contribution of these various metabolites to toxicity and efficacy of phenytoin is not well understood.

T.B. is found to carry a loss-of-function variant for *CYP2C9* with the genotype **1/*2*. With loss of CYP2C9 enzyme function comes decreased breakdown of the active drug phenytoin at standard doses. Given the narrow therapeutic index of phenytoin and the drug's propensity to cause side effects, T.B. ultimately experienced drug toxicity and accompanying symptoms. The evidence relating genotypes such as T.B.'s to the development of adverse drug events is strong, and CPIC has published dosing guidelines based on the *CYP2C9* genotype, summarized in **Table 4-4**.[40] Note that only the maintenance, not the loading dose, has adjustment recommendations so that acute seizure activity can be immediately terminated.

Table 4-4
***CYP2C9* Genotype–Based Dosing Recommendations for Phenytoin/Fosphenytoin**

***CYP2C9* Metabolizer Status**	**Sample Genotype(s)**	**Recommendation**
Extensive metabolizer	**1/*1*	Initiate therapy with recommended maintenance dose.
Intermediate metabolizer	**1/*2, *1/*3*	Consider *25% reduction* of recommended starting maintenance dose and adjust according to therapeutic drug monitoring and response.
Poor metabolizer	**2/*2, *3/*3, *2/*3*	Consider *50% reduction* of recommended starting maintenance dose and adjust according to therapeutic drug monitoring and response.

CASE 4-4

Question 1: J.P. is a 110.23-pound (50-kg), 17-year-old female status post kidney transplant. She is currently receiving azathioprine 100 mg by mouth (PO) daily to prevent rejection. She is brought to the emergency department 5 days after starting the medication with lethargy, fever, and malaise. A white blood cell (WBC) count comes back with a critically low value of 0.9×10^9 cells/L (normal range, $4.5–11.0 \times 10^9$ cells/L), with an absolute neutrophil count (ANC) of 760 cells/μL (normal range, 2500–6000).

What factors might explain such severe neutropenia, and what pharmacogenomic test should be ordered for J.P.?

Azathioprine is an immunosuppressive agent in the thiopurine class, acting as a prodrug of 6-mercaptopurine. These drugs are purine analogs and antagonize purine synthesis, inhibiting synthesis of DNA, RNA, and proteins.[41] Thiopurines are used in a variety of conditions including renal transplant, rheumatoid arthritis, certain cancers, and inflammatory bowel disease.

Azathioprine is further metabolized to 6-mercaptopurine (an active drug) via glutathione S-transferase (GST) reduction. 6-Mercaptopurine is then converted into the active 6-methylmercaptourine ribonucleotide (6-MMPR) and several inactive metabolites such as 6-methylmercaptopurine (6-MMP) through multiple pathways.[42] The two primary enzymes contributing to 6-mercaptopurine breakdown are TPMT and hypoxanthine guanine phosphoribosyltransferase (HPRT). TPMT metabolism results in the generation of the inactive metabolite 6-MMP, whereas HPRT contributes to a pathway that leads to the generation of active 6-MMPR and 6-thioguanine nucleotide (6-TGN) metabolites.[43] Furthermore, active 6-TGN metabolites are then inactivated by TPMT. The accumulation of active 6-TGN metabolites via HPRT is associated with myelosuppression with thiopurine therapy. In summary, TPMT acts as the detoxifying enzyme for drugs in the thiopurine class, and its activity is directly linked to risk of drug toxicities.

The severe neutropenia J.P. experienced 5 days after beginning azathioprine is very likely the result of starting a full dose (2 mg/kg/day) in the setting of a homozygous variant *TPMT* genotype,

such as **3B/*3C*. Owing to the near-absent enzyme level produced by homozygous variants, the TGN metabolites build up, resulting in severe, and sometimes, life-threatening neutropenia.

It is important to note that the genotype **3B/*3C* is nearly impossible to distinguish from the less clinically impactful heterozygous genotype of **1/*3A* on most commercially available *TPMT* assays. In cases of suspected homozygous variant status, parental studies may be necessary for absolute determination. Alternative therapy or a 90% reduction in the azathioprine dose is advised for J.P.'s *TPMT* genotype. In the case of a heterozygous genotype such as **1/*3C*, the dose would be decreased by 30% to 70%.[44]

DRUG TARGET IMPLICATIONS

CASE 4-5

Question 1: L.K. is a 45-year-old female referred for interpretation of pharmacogenomic results provided by a certified clinical lab as part of a research study. The report states that her genotype for *SLCO1B1* is CC. L.K. asks if she is at risk for severe muscle pain, or myopathy, with statin therapy that she heard about on a recent TV malpractice commercial.

What information do you need to answer her question?

"Statins" or β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor drugs are associated with muscle toxicity ranging from mild aches to the development of severe debilitating myopathy and rhabdomyolosis in a segment of the population.[45] Regardless of severity, this adverse drug event is a common cause for drug discontinuation.[46] Recent published literature links the risk of developing these muscle-related side effects to certain variants in the *SLCO1B1* gene.

Keeping in mind that a raw result from DNA analysis is essentially a string of As, Cs, Ts, and Gs within each individual gene, the CC genotype for *SLCO1B1* information provided by L.K. is insufficient.

To accurately review the available evidence and make recommendations, it is essential to know the actual variant location that the CC call was based on. Although there are multiple polymorphisms that have been identified in the *SLCO1B1* gene, only a few are linked to clinical effect.[46]

An rs number, or rsID, is used to point to a specific nucleotide location within a gene. Known SNPs within a gene are defined by rsID for the purpose of clinical guidelines and research reporting. This ensures standardization and proper assessment of variants. For *SLCO1B1*, the rsID most commonly associated with development of myopathy with HMG-CoA reductase inhibitors is rs4149056.[46] This rsID should be provided with results to make the proper assessments, and most clinical labs will include the associated rsID numbers for any SNP results to help clinicians make appropriate decisions about drug selection and dose alteration.

Case 4-5, Question 2: The clinical lab confirms the *SLCO1B1* genotype CC call was based on rs4149056. What is your answer to L.K.'s question regarding her risk of developing severe myopathy with statin use?

The C allele at *SLCO1B1* rs4149056 has been associated with decreased statin intracellular transport and clearance.[46] SLCO1B1 is a transporter protein with a primary function of drug uptake into the liver. Variants affecting the hepatic uptake of drugs via SLCO1B1 ultimately increase overall area under the curve (AUC) and drug exposure, resulting in higher risks of adverse drug events such as myopathy. Patients with a homozygous variant status such as L.K. are at significantly increased risk for developing muscle toxicity with statin use. Although all statins may have adverse event profiles linked to this variant, the evidence is strongest for simvastatin. Published CPIC guidelines for simvastatin with SLCO1B1 rs4149056 variant status are summarized in **Table 4-5**.

Table 4-5
***SLCO1B1* Genotype–Based Dosing Recommendations for HMG-**

CoA Reductase Inhibitors

SLCO1B1 rs4149056 Genotype	Myopathy Risk With Simvastatin Use	Simvastatin Dosing Recommendation
TT	Normal	Prescribe standard starting dose and modify based on tolerance and disease response.
TC	Intermediate	Prescribe a lower dose or consider alternative statin (such as pravastatin or rosuvastatin). Routine monitoring of CK may be considered.
CC	High	Prescribe a lower dose or consider alternative statin (such as pravastatin or rosuvastatin). Routine monitoring of CK may be considered.

CK, creatine kinase; HMG-CoA, β-hydroxy-β-methylglutaryl-coenzyme A.

NONMETABOLIC IMPLICATIONS

CASE 4-6

QUESTION 1: J.C. is an 18-year-old female with a past medical history of epilepsy. Following a failed course of levetiracetam, her physician has decided to start her on carbamazepine therapy for seizure control. Approximately 2 months after starting the drug, J.C. has been seizure free but started feeling flu-like symptoms with a headache and fever. She also noticed that her skin was becoming red and itchy in several locations. The rash quickly progressed to the point where she notes swelling and the formation of blisters on her nostrils, eyes, and lips. J.C. then realized that she might be experiencing something more than a common rash and called the pharmacy in a panic to ask if it was possible that she is reacting to her medication, even though she had been on it for some time.

Given the known side effects of carbamazepine, is it possible that J.C. is experiencing a drug reaction?

ADRs are often thought to happen soon after initial doses of medication. However, delayed hypersensitivity is also possible. In the case of carbamazepine, these reactions are linked to DNA changes within the human leukocyte antigen (*HLA*) genes. There is a strong association between positive *HLA-B*1502* gene variant carrier status and increased risk of severe cutaneous adverse reactions.[47] A less-established link has also been seen with carriers of the *HLA-A*31:01* variant, more common in Japanese and Europeans.[48]

The *HLA* genes code for proteins that form an immunologic complex found on all nucleated cells. This complex is responsible for presenting both self and foreign peptides to immune cells, such as T cells.[49] When a foreign peptide is presented and then recognized by a T cell, there is an immunologic response. Examples of peptides that may be recognized as foreign include viruses, bacteria, tumor antigens, and drugs. Although this complex may play a role in drug-induced reactions seen with *HLA* variants, there is still significant uncertainty as to whether or not there are other mechanisms at play.[50] Evidence has suggested that drug concentrations are also higher in patients who experience cutaneous reactions, hinting that CYP loss-of-function alleles and *HLA* variants may work synergistically to increase a patient's risk of SJS and TEN.[50] This possibility is supported by the fact that not all patients who carry an *HLA* allele will experience a cutaneous reaction.[47]

HLA class I genes are highly polymorphic.[51] Variants within these genes are thought to result in structural changes in the HLA complex that increase the recognition and subsequent response of the immune system to certain drugs, resulting in hypersensitivity. Reactions related to these variants tend to be dermatologic in nature with or without systemic involvement, ranging from a mild maculopapular rash or progressing to more severe cases of SJS and TEN.

Case 4-6, Question 2: What is the appropriate advice for the pharmacist to provide to J.C. given her presentation?

J.C. should be advised to seek care immediately at the closest and most accessible hospital emergency department. SJS and TEN have significant associated complications and typically require inpatient treatment with fluids, corticosteroids, analgesics, nutritional supplementation, and antibiotics. Mortality rates with TEN are estimated to be >30%.[48] In all cases, the suspected offending agent should be discontinued with no rechallenge.

Case 4-6, Question 3: In questioning J.C., the pharmacist learns that she has no prior history of adverse drug or food reactions. She is of Chinese descent and has never had genetic testing. What would have been an appropriate course of action for a patient with J.C.'s history before starting carbamazepine therapy?

Differing from CYP enzyme genotypes, HLA phenotypes do not lie on a spectrum, and patients are reported as positive if at least one variant is present or negative if no variant is present. Carriers of certain *HLA* variants are at increased risk for cutaneous ADRs; however, recommendations and guidelines for preemptive testing are either nonspecific or lacking. Other *HLA* variants have been linked to liver injury, leading to the theory that the amount and location of HLA expression may be a determining factor relating to which organ systems are affected.[51] Determining when and whom to test before therapy is typically left to the discretion of the provider or institution-specific protocols. The exception to this is for the HIV drug abacavir, for which CPIC and the U.S. Food and Drug Administration (FDA) recommendations state that all patients should have *HLA-B*57:01* testing before initiating regimens with either of these therapies.[52]

Variants of the *HLA* genes are seen more commonly within certain ethnicities. In some cases, owing to the high prevalence of allele carrier status in these populations, patients with particular ethnic backgrounds may be recommended for testing. Certain Asian populations are known to have higher rates of certain variants, warranting caution when using certain therapies (**Table 4-6**). In the case of carbamazepine and J.C., her physician may have justifiably

ordered pharmacogenomic testing to determine her *HLA-B*15:02* carrier status based on the fact that she identifies as Chinese. Relying on self-reported ethnicity can be problematic, however, because many people are not fully knowledgeable of their complete lineage.

Table 4-6
***HLA* Variants, Affected Drugs, and Population Incidence**

***HLA* Variant**	**Drugs With Associated Adverse Cutaneous Reactions**	**Highest Variant Frequencies by Ethnicity[48,54–57]**
*HLA-B*57:01*	Abacavir	Caucasian: 5%–8%
*HLA-B*58:01*	Allopurinol	Han Chinese: 6%–8% Korean: 12%
*HLA-B*15:02*	Phenytoin, carbamazepine	Han Chinese: ~10% Populations from Hong Kong, Thailand, Malaysia, Vietnam, Philippines, India, and Indonesia: >5%
*HLA-A*31:01*	Carbamazepine	Northern European: 2%–5% Japanese: up to 17.5%

HLA, human leukocyte antigen.

Clinical Pharmacogenetics Implementation Consortium guidelines for HLA-B genotype and abacavir dosing: 2014 update. *Clin Pharmacol Ther*. 2014;95(5):499–500. doi:10.1038/clpt.2014.38; Saito Y, Stamp LK, Caudle KE, et al. Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines for human leukocyte antigen B (HLA-B) genotype and allopurinol dosing: 2015 update. *Clin Pharmacol Ther*. 2016;99(1):36–37. doi:10.1002/cpt.161.

Testing recommendations vary, but if a patient is a known carrier of an *HLA* variant, it is recommended that they avoid the use of

drugs for which there is an *HLA*-variant–associated risk of adverse reaction.[40,47,52,53]

CYP2D6 PECULIARITIES

CASE 4-7

Question 1: P.F. is a 37-year-old-female with a history of depression and anxiety who presents to the local pharmacy with a printed report from a for-profit pharmacogenomic testing company. The report states that P.F. is an extensive metabolizer for CYP2D6, and she is concerned that her paroxetine is still not providing any relief of her depressive symptoms despite having taken the drug correctly for the past 3 months.

What information would you want to know about the testing modality the company used before answering her question regarding the interpreted genotype?

There are several pharmacogenomic testing platforms, with the majority of commercially available panels being SNP based. The advantages of SNP-based platforms include lower cost, faster turnaround time, vendor-provided interpretation software, and reliable calling for known variants. The main disadvantage of SNP-based platforms is that they are only capable of delivering results for the genes and specific variants on the panel. If a person carries any unique or rare variants, the SNP-based panel will not detect them. This scenario increases the risk of there being a discrepancy between a patient's reported genotype and phenotype, or how they actually process and/or respond to drugs affected by the variant. *CYP2D6* is also a very polymorphic gene, and it is not uncommon for individuals to carry more than two allele copies. Differences in the *CYP2D6* copy number is referred to as *copy number variation (CNV)*, and knowing the CNV is extremely important in interpreting a person's *CYP2D6* genotype.[58] Once CNV is determined, all of the allele copies identified should be genotyped, which is not always possible on commercially available assays because the process

requires extra primers. Another issue is that *CYP2D7* is a pseudogene (a gene with no function) that can accidentally be included in the *CYP2D6* analysis if the assay is not designed correctly.[59]

In addition to targeted SNP-based assays, pharmacogenetic data can come from other types of genetic tests. The coding region of DNA is the exome, and whole-exome sequencing or assays targeting specific regions of interest within the exome can provide significant pharmacogenomic data. With exome sequencing, uncommon or previously unidentified variants could be reported, often deemed variants of unknown significance (VUS) because their clinical effects are not yet known. Because there remains a lot of variability in how exomes are analyzed and reported, both sensitivity and specificity of results are mutable. As a result, it can be a challenge to manage and meaningfully interpret exome findings, particularly when a distinct phenotype cannot be readily correlated. In addition, exome- and whole-genome sequencing can yield incidental or secondary findings of disease-state markers. The hybrid test, a sequence-based targeted panel of pharmacogenes, has become a hot area of development, attempting to incorporate the best features of both sequencing and limited gene interrogation.

P.F.'s report shows a genotype of *CYP2D6 *1/*2* but does not indicate the copy number of the *CYP2D6* gene. This is a red flag for interpretation and should prompt the pharmacist to call the company to obtain a detailed explanation of the assay used and understand how P.F.'s extensive metabolizer phenotype was determined.

Case 4-7, Question 2: Per the company, P.F.'s copy number was equal to 3. Does this information change the interpretation of P.F.'s phenotype?

A *CYP2D6* copy number of 3 with **1/*2* alleles is associated with the ultrarapid metabolizer phenotype.[58] Unique to *CYP2D6*, an activity score is calculated based on the number of copies of the gene present because all influence drug metabolism. The activity score was introduced by Gaedigk in 2013 to better categorize the

metabolism status of persons with extra copies of the gene.[60] An example of how CNV can change a phenotype is represented in **Table 4-7**.

Table 4-7
***CYP2D6* Genotypes, Phenotypes and Activity Scores**[58-60]

Number of Copies	Genotype	Activity Score	Phenotype
1	*1/*5	1	Intermediate metabolizer
2	*1/*2	2.0	Normal metabolizer
>2	*1/*2	>2.0	Ultrarapid metabolizer

Gaedigk A. Complexities of CYP2D6 gene analysis and interpretation. *Int Rev Psychiatry*. 2013;25(5):534–553. doi:10.3109/09540261.2013.825581; Riffel AK, Dehghani M, Hartshorne T, et al. CYP2D7 sequence variation interferes with TaqMan CYP2D6 (*) 15 and (*) 35 genotyping. *Front Pharmacol*. 2015;6:312. doi:10.3389/fphar.2015.00312; Caudle KE, Sangkuhl K, Whirl-Carrillo M, et al. Standardizing CYP2D6 genotype to phenotype translation: consensus recommendations from the clinical pharmacogenetics implementation consortium and Dutch Pharmacogenetics Working Group. *Clin Transl Sci*. 2020;13(1):116–124. doi:10.1111/cts.12692.

As an ultrarapid metabolizer, P.F.'s lack of response to a standard paroxetine dose aligns with her phenotype. Per the associated CPIC guideline, her provider should choose another drug not primarily metabolized via the CYP2D6 pathway.[61] Because P.F. spent 3 months taking a medication with no response, this case serves as a prime example of the important role pharmacogenomic data can play in guiding treatment choices before initiating therapy.

CASE 4-8

QUESTION 1: You have started to work at a pediatric hospital and notice that codeine is not orderable in the electronic medical record. When you ask a coworker, he informs you that the black box warning placed on all codeine products by the FDA in 2012 has resulted in the majority of pediatric institutions removing the drug from formularies.

What specific genotype is correlated with the risk of life-threatening apnea with codeine use?

Codeine is metabolized by CYP2D6 to the active metabolite morphine, which provides analgesic properties. CYP2D6 ultrarapid metabolizers can generate morphine at higher rates, exceeding the body's ability to convert it to less toxic metabolites and resulting in life-threatening apnea.[62] Approximately 4% of the population are thought to be CYP2D6 ultrarapid metabolizers.[63]

In contrast, there are several loss-of-function variants across ethnicities that confer little to no CYP2D6 enzyme function, resulting in a lack of morphine formation. The loss-of-function **4* allele, for example, is found in 6% of African Americans, 5% of Asians, and in up to 18% of European Americans/Europeans.[63] Patients carrying loss-of-function *CYP2D6* alleles are likely to show decreased response to codeine.[64]

IMPACT OF PEDIATRIC ENZYME DEVELOPMENT ON PHARMACOGENOMICS

CASE 4-9

QUESTION 1: As part of a voluntary research study in the neonatal intensive care unit (NICU), pharmacogenomic results are returned to the provider for an ex-30 week, 36.5-week corrected gestational age female. The provider notes that her genotype for CYP2C19 is *17/*17, which would typically indicate that she is an ultrarapid metabolizer for this enzyme. The provider states he would like to start her on voriconazole for a presumed fungal infection and asks what the dosing should be given her genotype.

What other information would be necessary to recommend a voriconazole dose for this infant?

Voriconazole is metabolized via multiple enzyme pathways including CYP3A4, CYP2C9, and CYP2C19, with the most significant contribution coming from CYP2C19.[65] The Royal Dutch

Pharmacists Association has guidelines in place recommending monitoring of voriconazole serum concentrations for CYP2C19-poor and CYP2C19-intermediate metabolizers because these patients have been found to have higher concentrations of active drug and increased risk of toxicity. The consideration for a person with the *CYP2C19 *17/*17* is the potential for increased breakdown of active drug and treatment failure.[66]

Given this patient's young age, multiple complex factors need to be considered for dosing, both genetic and nongenetic. Because voriconazole is dosed by body weight, the actual body weight of the child is necessary for an appropriate dose calculation. Drug–drug interactions should also be considered if the patient is taking medications that induce or inhibit enzymes in the drug's pathway. Other variables contributing to complicated infant dosing and clearance unpredictability include developing GI and renal function and fluctuations in body fat and water composition affecting density of drug distribution.[67] In addition, although the patient's genotype suggests she will have increased breakdown of the active drug, it is known that, regardless of genotype, humans are not born with fully functional CYP enzymes.[67,68]

CYP enzyme development occurs at variable rates over time, making it difficult to determine the contribution of pharmacogenomic variants on optimal dosing (**Fig. 4-3**).[69-71] An excellent summary review of enzyme maturation by Kearns and colleagues was published in the *New England Journal of Medicine* in 2003.[67] CYP1A2, for example, is virtually undetectable at birth, with initial development of low-level enzyme concentrations being seen over the first month of life. Although general trends are observed, it is also understood that development rates vary among individuals throughout childhood, particularly in the first year of life.[67] Given this consideration, pharmacogenomics in the neonatal and infant population may be a less influential factor than it is in older children and adults, and its overall contribution remains unpredictable because few studies are dedicated to the effects of pharmacogenomic variants in the youngest patients. Therefore, it is particularly important to monitor drug concentrations, response, and

toxicities in the younger pediatric population and to dose adjust accordingly. Voriconazole is of particular concern with this group because evidence suggests that current pediatric dosing recommendations could lead to subtherapeutic concentrations and a general increased risk of treatment failure.[72]

FAMILIAL IMPLICATIONS OF PHARMACOGENETICS

CASE 4-10

QUESTION 1: H.T. is a 12-year-old female who had an operation resulting in the development of malignant hyperthermia (MH). Following recovery, she is found to have a pathogenic SNP variant (mutation) at the 7300 nucleotide (referred to as c.7300G>A) in the *RYR1* gene, a common variant associated with predisposition to MH. H.T.'s providers discuss the influence of this finding on her future medical and drug management.

What additional clinical considerations should her providers address following H.T.'s genetic findings and presentation?

Genes are inherited, so any discussion relating to clinically significant genetic variants should also include raising awareness of the variant's implications beyond the patient who was tested. In the case of H.T., the mutation associated with MH is dominant, the clinical consequence can be life-threatening, and the likelihood of inheritance is high. Counseling and testing of parents and extended family members could therefore be recommended. When an individual is being counseled on pharmacogenomic testing results before any related incident, it is important to raise the possibility that the results could have implications for the greater family.[73]

MAKING THE CASE FOR PHARMACOGENOMICS

In general, several studies have shown that patients are more adherent with their medication regimes after receiving personalized genotyping results, even if the findings show "normal" enzyme function.[74] Because medication adherence is an ongoing challenge in optimizing patient care, pharmacogenomic testing could offer a potential incentive.

An increased understanding of pharmacogenomics has also allowed pharmaceutical companies to design and develop drugs that specifically target protein changes associated with certain mutations, making regimens more personalized and effective. To determine whether a patient will benefit from these targeted therapies,

companion tests (pharmacogenetic assays that target the variants of interest) are usually required. A pharmacist must understand which medications require companion testing and know how to interpret and apply the associated results. Possible hurdles for companion testing requirements by drug manufacturers may include the potential wait time in getting insurance approval for the companion test that could delay care.

CASE 4-11

QUESTION 1: K.D. is a 22-year-old female with cystic fibrosis. Her pulmonologist is interested in prescribing the drug ivacaftor. K.D. comes to the pharmacy and mentions the need for a special test before starting this new treatment, but she cannot remember why the test is necessary.

What test is K.D. likely getting to determine whether she is eligible to receive ivacaftor?

Ivacaftor (Kalydeco®) is a drug used to treat cystic fibrosis, and it acts at the cystic fibrosis transmembrane conductance regulator (CFTR) channel. CFTR protein is found on a variety of tissue surfaces, including the lungs. When functioning properly, the CFTR protein is a key component in maintaining intracellular salt balance.[75] Cystic fibrosis results from a variety of possible genetic mutations, causing dysfunctional CFTR protein and leading to fluid imbalances, the buildup of secretions, and several related complications.

Kalydeco® is an oral agent approved for patients with cystic fibrosis carrying 10 specific variants in the *CFTR* gene: *G551D*, *G1244E*, *G1349D*, *G178R*, *G551S*, *R117H*, *S1251N*, *S1255P*, *S549N*, and *S549R*. For this subset of patients, the drug acts as a CFTR potentiator, increasing CFTR activity, restoring electrolyte balance, reducing the buildup of secretions, and improving health outcomes, such as pulmonary function and weight gain for affected patients.[76] For patients with cystic fibrosis affected by other mutations, the drug will be ineffective. K.D.'s doctor likely ordered a genetic test to determine which mutation was the cause of her cystic fibrosis diagnosis.

Ivacaftor was approved in 2012 for patients with the *G551D* mutation, offering promise for continued future development of therapies targeting the underlying causes of genetic diseases. This promise remains encouraging because the use of ivacaftor has since been approved in the treatment of several additional gene mutations. In addition, new similar targeted therapies such as lumacaftor (Orkambi™), a CFTR corrector, and combination products such as elexacaftor/tezacaftor/ivacaftor (Trikafta™) continue to enter the market.[77]

Another potential use of pharmacogenomics involves salvaging drugs with high toxicity profiles. Historically, many drugs have been taken off the market after an unacceptable number of patients either suffered significant morbidity or mortality secondary to the use of the drug. In some cases, pharmacogenomic studies may be able to determine which patients could continue to benefit from the drug and which patients should avoid use.

Despite the many advances in testing and clinical application, preemptive pharmacogenomic testing before the development of an adverse effect or lack of response is not currently widely used, for several reasons. A major barrier comes from the fact that health care professionals, including pharmacists, lack the knowledge necessary to apply pharmacogenomic data. One recent study found that only 29% of the physicians surveyed received any formal education around pharmacogenomics, and only 10.3% felt knowledgeable enough to prescribe or discuss the results of pharmacogenomic testing.[78] Another large impediment to implementation is the lack of consistent reimbursement policies by insurance providers. To achieve widespread and consistent pharmacogenomic testing coverage by insurance companies, there is a need for concerted regulatory efforts and continued proof that pharmacogenomic testing improves outcome and decreases cost.[2,15,79]

At this time, the majority of preemptive pharmacogenomic testing is happening in places where there is institutional support of targeted program development, such as academic medical and cancer centers, or where programs can directly bill patients for services not

covered by insurance, as is seen with for-profit pharmacogenomic testing companies.

Case 4-11, Question 2: What references could be used to assist pharmacists and providers in interpreting pharmacogenomic results and applying any variant findings to subsequent drug dosing decisions?

The FDA and European Medicines Agency (EMA) currently list pharmacogenomic markers in 326 and 78 drug labels, respectively.[80,81] To be included in the FDA labeling, a pharmacogenomic marker must have known clinical consequence, such as an increase in adverse effects or reduction in efficacy, or actionable recommendations for alternative treatment or dose modification. In addition, as referenced earlier, PharmGKB, CPIC, and DPWG provide a valuable and accessible resource for pharmacists.

Incorporating pharmacogenomic data into electronic medical record systems is challenging. Result reports from laboratories capable of running these tests are rarely in a machine-readable format and are generally delivered as PDF documents to be scanned into a patient's chart.[82] This scenario presents a major systemic challenge in being able to provide relevant pharmacogenomic data at the time they are most needed, during the drug prescribing and dispensing processes. Pharmacogenomic results remain relevant throughout a person's lifetime and require significant bioinformatics expertise to house, retrieve, interpret, and present to the end user at the right time.[83] To ensure that the most recent variant knowledge is being applied, it is also important to track the evolution of testing options over time. It is possible that updated analyses could be needed, such as sequencing a new sample or reprocessing a previous sample with new algorithms. A payment model for reinterpretation without retesting is extremely uncommon in the field of laboratory medicine today.

Other extremely important considerations around housing, storing, and using pharmacogenomic data include security and privacy. Data

security refers to protection of information from breaches and inadvertent dissemination, whereas data privacy relates to respecting patient preferences for data sharing, both with the patient directly as well as with the larger health care community. The recent European Union (EU) implementation of the General Data Protection Regulation (GDPR) is of particular interest in this realm given its focus on digital data (https://gdpr-info.eu/ [accessed February 15, 2022]). The GDPR was designed to ensure that personal data are gathered legally and under strict conditions. In addition, those who collect and manage personal data are obliged to protect it from misuse and exploitation, as well as to respect the rights of data owners with reach beyond the EU.

Ultimately, how is the decision made to offer and incorporate pharmacogenomic testing into practice? In a nonideal scenario, health care providers have no choice when patients hand them a printed report from direct-to-consumer pharmacogenetic testing services. These patients look to their health care team to consider the results when prescribing and dispensing decisions are made, making pharmacogenomic knowledge critical. Academic medical programs have begun to incorporate pharmacogenomic science into core curricula, but it is often in the form of a single 1- to 2-hour lecture. This level of training will be inadequate in preparing providers to deal with the era of personalized medicine and the eventual day when everyone will have access to their own genomic data.

When assessing the value of incorporating pharmacogenomic testing into practice, several factors impact the return on investment and influence on clinical outcomes. These factors include, but are not limited to, the number of patients needed to be tested to find one patient with an actionable variant, ethnic variation given that populations are now blended and clear ancestry knowledge is often lacking, the cost of testing, the likelihood of insurance reimbursement, and the cost savings offset by averting serious adverse reactions or nonresponse.[79]

Genetic testing can also introduce challenging ethical questions, particularly when dealing with broader tests covering large sections

of DNA such as whole-exome or whole-genome sequencing. Although most people want to know whether they should take a medication, many do not wish to know their risk of developing Alzheimer disease or breast cancer. The American College of Medical Genetics (ACMG) updated a position statement relating to this topic in 2021, listing a total of 73 genes with pathogenic variants causing specific defined diseases when tested, irrespective of the age of the patient.[84] However, consent should be obtained to fully inform the patient and/or their parent(s)/legal guardian(s) of the implications, including with respect to the risks to them and their relatives of developing the disorders and the potential for insurance discrimination based on pathogenic findings.[85,86] Although the 2008 Genetic Information Nondiscrimination Act (GINA) makes it illegal for health insurance coverage to be denied because of genetic findings, there is no protection for life or long-term care insurance coverage.[87]

CONCLUSION

Pharmacogenomics is simultaneously an exciting and a challenging component of personalized medicine and the practice of pharmacy. One of the most important points to remember when working with pharmacogenomic data is that they serve as an additional clinical marker but are rarely the only answer. A patient's organ function, disease state, diet, smoking status, other environmental factors, and drug–drug interactions play a very large role in the disposition of drugs. Age-based maturation of enzyme function must also be accounted for when determining the impact of the genotype on drug metabolism in younger pediatric patients.

Pharmacists are uniquely qualified to interpret and apply pharmacogenetic findings to medication selection and dosing decisions. To adequately fulfill this role in a clinical setting, pharmacists need focused education on the topic of pharmacogenomics, understanding of how to apply validated algorithms, access to continually updated literature, and a

partnership with genetic experts, including geneticists and genetic counselors.[88] This chapter has only briefly touched upon examples of actionable pharmacogenes. The following key references and websites provide extensive information for further study.

Managing Drug Overdoses and Poisonings

Iris Sheinhait

CORE PRINCIPLES

GENERAL MANAGEMENT

CHAPTER CASES

1 The most important aspect of patient management is to support airway, breathing, and circulation (the “ABCs”). There is no “cookbook” method to treat all poisoned patients, so it is important to treat the patient, not the poison or the laboratory values. The assessment and treatment of the potentially poisoned patient can be separated into seven functions: (a) gather history of exposure, (b) evaluate clinical presentation (ie, “toxidromes”), (c) evaluate clinical laboratory patient data, (d) remove the toxic source (eg, irrigate eyes,

Case 5-4 (Questions 1, 3, 5, 6)

decontaminate exposed skin), (e) consider antidotes and specific treatment, (f) enhance systemic clearance, and (g) monitor patient outcome.

GASTROINTESTINAL DECONTAMINATION

1

The most appropriate method for gastrointestinal (GI) tract decontamination is unclear because sound comparative data for different methods of GI decontamination are not available. Lavage, emesis, and cathartics are rarely performed because there is no evidence that they improve patient outcome. Activated charcoal is generally safe to use, but it should not be administered if the benefit is not greater than the risk. Whole-bowel irrigation using a polyethylene glycol–balanced electrolyte solution can successfully remove substances (iron, lithium, sustained-release dosage forms) from the entire GI tract in a period of several hours.

Case 5-3 (Questions 6, 7)
Case 5-4 (Questions 11, 12, 16)
Case 5-5 (Question 3)

ANTIDOTES

1

An antidote is a drug that reverses the toxicity of another substance. Some antidotes displace drugs from receptor sites (eg, naloxone for opioids, flumazenil for benzodiazepines), and some can inhibit the formation of toxic metabolites (eg, *N*-acetylcysteine [NAC]

Case 5-4 (Questions 2, 4)

for acetaminophen, fomepizole for ethylene glycol and methanol).

TOXICOLOGY LABORATORY SCREENING

1

Urine drug screens can be useful in a patient with coma of unknown etiology, when the presented history is inconsistent with clinical findings, or when more than one drug might have been ingested. Qualitative screening is intended to identify unknown substances involved in the toxic exposure. A benzodiazepine screen can detect oxazepam, a common benzodiazepine metabolite, but it will not detect alprazolam and lorazepam because they are not metabolized to oxazepam. Opioid screens may not detect synthetic opioids such as fentanyl and methadone. Quantitative testing determines how much of a known drug is present and can help determine the severity of toxicity and the need for aggressive interventions (eg, hemodialysis in ethylene glycol, methanol, and salicylate).

Case 5-4 (Questions 1, 7, 8)

TOXIDROMES

1

A toxidrome is a consistent constellation of signs and symptoms associated with some specific classes of drugs. The most common toxidromes are those associated with anticholinergic activity, increased sympathetic activity, and

Case 5-4 (Questions 1, 2, 5)

central nervous system (CNS) stimulation or depression. Anticholinergic drugs increase heart rate and body temperature, decrease GI motility, dilate pupils, and produce drowsiness or delirium. Sympathomimetic drugs increase CNS activity, heart rate, body temperature, and blood pressure. Opioids, sedatives, hypnotics, and antidepressants depress the CNS, but the specific class of CNS depressants often cannot be easily identified.

SALICYLATES

1 Acute ingestion of 150 to 300 mg/kg aspirin causes mild-to-moderate intoxication, >300 mg/kg indicates severe poisoning, and >500 mg/kg is potentially lethal. Symptoms of intoxication include vomiting, tinnitus, delirium, tachypnea, metabolic acidosis, respiratory alkalosis, hypokalemia, irritability, hallucinations, stupor, coma, hyperthermia, coagulopathy, and seizures. Salicylate intoxication mimics other medical conditions and can be easily missed. Patients with a chronic salicylate exposure, acidosis, or CNS symptoms, and those who are elderly are at high risk and should be considered for early dialysis.

Case 5-1 (Questions 1–3)
Case 5-2 (Questions 1–6)

IRON

1	Acute elemental iron ingestions of <20 mg/kg are usually nontoxic; doses of 20 to 60 mg/kg result in mild-to-moderate toxicity, and doses of >60 mg/kg are potentially fatal. Symptoms of toxicity include nausea, vomiting, diarrhea, abdominal pain, hematemesis, bloody stools, CNS depression, hypotension, and shock. Patients with severe iron poisoning do not exhibit the second stage of the so-called recovery but continue to deteriorate.	**Case 5-3 (Questions 1–14)**

TRICYCLIC ANTIDEPRESSANTS

1	Severe toxicity has been associated with doses of 15 to 25 mg/kg. Symptoms include tachycardia with prolongation of the PR, QTc, and QRS intervals; ST and T-wave changes; acidosis; seizures; coma; hypotension; and acute respiratory distress syndrome. A QRS segment >100 milliseconds is commonly seen in severe tricyclic antidepressant overdoses.	**Case 5-4 (Questions 9–17)**

ACETAMINOPHEN

1	Toxicity is associated with acute ingestions >150 mg/kg or >7.5 g total in adults. Symptoms in patients with toxicity include vomiting, anorexia, abdominal pain, malaise, and progression to characteristic centrilobular hepatic necrosis.	**Case 5-5 (Questions 1–15)**

Acetaminophen-induced hepatotoxicity is universal by 36 hours after ingestion, but patients who receive NAC within 8 to 10 hours of ingestion rarely exhibit hepatotoxicity. There is no consensus as to the best route of NAC administration, the optimal dosage regimen, or the optimal duration of therapy.

INTRODUCTION

This chapter reviews common strategies for the evaluation and management of drug overdoses and poisonings. Information regarding the management of specific drug overdoses is best obtained from a poison control center (reached by calling 1-800-222-1222 anywhere in the United States).

Epidemiologic Data

AMERICAN ASSOCIATION OF POISON CONTROL CENTERS AND DRUG ABUSE WARNING NETWORK

Toxicity secondary to drug and chemical exposure commonly occurs in children. The incidence of exposure to specific agents and the severity of outcomes vary based on the population studied.[1–3] The number of reported toxic exposures in the United States in 2018 was ~2.1 million, according to the American Association of Poison Control Centers (AAPCC).[3] Approximately 70% of the reported cases were treated at home, saving millions of dollars in medical costs.

According to the Drug Abuse Warning Network, almost 5.1 million U.S. emergency department (ED) visits involved drug misuse or abuse in 2011. Illicit drugs include cocaine, heroin, marijuana,

ecstasy, γ-hydroxybutyric acid, flunitrazepam (Rohypnol®), ketamine, lysergic acid, phencyclidine, and hallucinogens. Of those cases, illicit drug use was mentioned >2.7 million times because many of the visits involved multiple drugs of abuse.[4]

AGE-SPECIFIC DATA

Stratifying patients by age can be useful in assessing the likelihood of severe toxicity from an exposure. Most unintentional ingestions by children ages 1 to 6 years occur because children are curious, becoming more mobile, and beginning to explore their surroundings, and they often put objects or substances into their mouths.[5] Severe toxicity in young children is relatively uncommon because exposures usually involve the ingestion of relatively small amounts of a single substance.[5,6] AAPCC epidemiologic data also report medication errors, which in the pediatric population commonly result from confusing units of measurement (eg, teaspoons vs milliliters or tablespoons vs teaspoons), incorrect formulation or concentration administered, dispensing cup errors, and incorrect formulation or concentration dispensed from the pharmacy.[3]

In children older than age 6 years, the reasons for toxic exposure to medications are less clear.[7] Adolescent children generally have poor knowledge of the toxicity of medications and can overdose themselves unintentionally.[5,8] The potential for suicide attempts or intentional substance abuse should not be ignored in older children. These intentional overdoses commonly involve mixed exposures to illicit drugs, prescribed medications, or ethanol and are associated with more severe toxicity and death than with unintentional toxic exposures.

In geriatric patients, overdoses tend to have a greater potential for severe adverse effects compared with overdoses in other age groups.[9] Although the elderly constitute 13% of the population, they account for 33% of the drug use and 16% of the suicides.[10] Patients ages 65 years and older take an average of 5.7 prescription medications along with two to four nonprescription drugs daily.[9,10] The elderly are more likely to have underlying illnesses and often

have access to a variety of potentially dangerous medications. This results in higher rates of completed suicides than that in other age groups.[10,11]

Information Resources

COMPUTERIZED DATABASES

A vast number of substances can be involved in a poisoning or overdose. Reliable data about the contents of products, toxicities of substances, and treatment approaches need to be readily accessible. POISINDEX, a computerized database,[11] provides information on thousands of drugs by brand name, generic name, and street name, as well as foreign drugs, chemicals, pesticides, household products, personal care items, cleaning products, poisonous insects, poisonous snakes, and poisonous plants. Annual subscriptions to POISINDEX are expensive and are generally available only in large medical centers.[12]

PRINTED AND ELECTRONIC PUBLICATIONS

Textbooks and manuals also provide useful clinical information about the presentation, assessment, and treatment of toxicities. *Goldfrank's Toxicologic Emergencies*[13] and *Poisoning and Drug Overdose*[14] are valuable, less-expensive alternatives to computerized database programs, and are available in print and electronically. Books, however, are less useful than are computerized databases because information must be condensed and cannot be updated as frequently. Some drug package inserts also refer to treatment of acute toxicities; however, the information can be inadequate or inappropriate.[15,16]

POISON CONTROL CENTERS

Poison control centers provide the most cost-effective and accurate information to health care providers and to the general public.[17,18] Poison centers are staffed by trained poison information specialists who have a pharmacy, nursing, or medical background. Physician

backup is provided 24 hours a day by board-certified medical toxicologists. The nonphysician clinical toxicologists, pharmacists, and nurses who staff poison control centers are certified as specialists in poison information by the AAPCC or as clinical toxicologists by the American Board of Applied Toxicology.[19]

The poison information specialist must accurately and efficiently assess event-specific toxicity by telephone, without the benefit of direct observation of the patient. The specialist must communicate this assessment along with treatment information quickly, accurately, and professionally in a reassuring manner. Subsequent to telephone consultations, poison control center staff should initiate follow-up calls to determine the effectiveness of the recommended treatment and the need for additional evaluation or treatment.[20,21]

EFFECTIVE COMMUNICATION

Effective communication is essential to the assessment of potential poisonings. In most situations, the person seeking guidance on the management of a potentially toxic exposure is the parent of a small child who may have ingested a substance. The caller is usually anxious about the child and may feel guilty about the exposure. To calm the caller, the health care provider should quickly reassure the individual that telephoning for help was appropriate and that the best assistance possible will be provided.[21] If English is not the first language of the caller, or if there are other communication barriers (eg, panic), solutions must be found to enhance outcomes. Most poison centers subscribe to translation services or have bilingual staff to communicate with non–English-speaking callers. Poison centers also have special equipment to serve the hearing- and speech-impaired populations.

Once calm, effective communication is established, the health care provider should first determine whether the patient is conscious and breathing and has a pulse. If life-threatening symptoms have occurred, the caller should call 911 for emergency services. If the health care provider does not have the knowledge or resources to provide poison information, he or she should refer the caller to the

closest poison control center. Information on the location and phone number of the nearest poison control center can be found at http://www.aapcc.org or by calling 1-800-222-1222 in the United States.

GENERAL MANAGEMENT

Supportive Care and "ABCs"

Management of poisoned or overdosed patients is primarily based on symptomatic and supportive care. Specific antidotes exist only for a small percentage of the thousands of potential drugs and chemicals that can cause a poisoning.

The first aspect of patient management should always be basic support of airway, breathing, and circulation (the "ABCs"). The assessment and treatment of the potentially poisoned patient can be separated into seven primary functions: (a) gathering history of exposure, (b) evaluating clinical presentation (ie, "toxidromes"), (c) evaluating clinical laboratory patient data, (d) removing the toxic source (eg, irrigating eyes, decontaminating exposed skin), (e) considering antidotes and specific treatment, (f) enhancing systemic clearance, and (g) monitoring outcome.[22–24]

GATHERING EXPOSURE HISTORY

Comprehensive information about the history of the toxic exposure should be gathered from as many different sources as possible (eg, patient, family, friends, prehospital health care providers). This information should be compared for consistency and evaluated relative to clinical findings and laboratory results. The patient's history of the exposure is often inaccurate and should be confirmed with objective findings.[22,23,25] For example, a patient who presents to an ED with a supposed hydrocodone and carisoprodol overdose is expected to be lethargic or comatose. If the patient arrives wide

awake with tachycardia and agitation, the clinician should suspect exposure to other substances.

Specific information should be sought concerning the patient's state of consciousness, symptoms, probable intoxicant(s), and maximal amount and dosage form(s) of substance ingested, as well as when the exposure occurred. Medications, allergies, and prior medical problems also should be ascertained to facilitate development of treatment plans (eg, a history of renal failure may indicate the need for hemodialysis to compensate for decreased renal drug clearance).[22,23]

EVALUATING CLINICAL PRESENTATION AND TOXIDROMES

A thorough physical examination is needed to characterize the signs and symptoms of overdose, and it should be conducted serially to determine the evolution or resolution of the patient's intoxication. An evaluation of the presenting signs and symptoms can provide clues to the drug class causing the toxicity, confirm the data on the history surrounding the toxic exposure, and suggest initial treatment.[22,26–28] The patient may be asymptomatic on presentation, even though a potentially severe exposure has occurred, if absorption of the drug or toxic substance is incomplete or if the substance has not yet been metabolized to a toxic substance.[29–31]

Characteristic toxidromes (ie, a constellation of signs and symptoms consistent with a syndrome) can be associated with some specific classes of drugs.[23,27,28] The most common toxidromes are those associated with anticholinergic activity, increased sympathetic activity, and central nervous system (CNS) stimulation or depression. Anticholinergic drugs can increase heart rate and body temperature, decrease gastrointestinal (GI) motility, dilate pupils, and produce drowsiness or delirium. Sympathomimetic drugs can increase CNS activity, heart rate, body temperature, and blood pressure (BP). Opioids, sedatives, hypnotics, and antidepressants can depress the CNS, but the specific class of CNS depressant often cannot be easily identified.

Classic findings may not be present for all drugs within a therapeutic class. For example, opioids generally induce miosis, but meperidine can produce mydriasis. Furthermore, the association of symptoms with a particular class of toxic substances is difficult when more than one substance has been ingested. Practitioners should not focus only on the specific clinical findings associated with a toxidrome. Rather, they should consider all subjective and objective data gathered from the history of the exposure, the patient's medical history, physical examination, and laboratory findings.[27]

INTERPRETATION OF LABORATORY DATA

Drug screens

A urine drug screen can be useful in identifying the presence of drugs and their metabolites in selected patients but is not indicated in all cases of drug overdose. Urine drug screens can be useful in a patient with coma of unknown etiology, when the presented history is inconsistent with clinical findings, or when more than one drug might have been ingested.[32,33]

Pharmacokinetic considerations

The absorption, distribution, metabolism, and elimination of drugs in the overdosed patient can be quite different from when the drug is taken in usual therapeutic doses.[29–31] The expected pharmacodynamic and pharmacokinetic features of drugs can be substantially altered by large drug overdoses, especially with drugs that exhibit dose-dependent pharmacokinetics. The rate of drug absorption is generally slowed by large overdoses, and the time to reach peak serum drug concentrations can be delayed.[32,34] For example, peak serum concentrations of phenytoin can be delayed for 2 to 7 days after an orally ingested overdose.[35,36] The volume of distribution of an overdosed drug can be increased, and when usual metabolic pathways become saturated, secondary clearance pathways can be important. For example, large overdoses of acetaminophen saturate glutathione mechanisms of metabolism, resulting in hepatotoxicity.[37]

When the pharmacokinetic parameters of an overdosed drug are altered, serial plasma concentration measurements can better define the absorption, distribution, and clearance phases of the ingested substance. Pharmacokinetic parameters that have been derived from therapeutic doses should not be used to predict whether absorption is complete or to predict the expected duration of intoxication caused by large overdoses.[31,38,39]

DECONTAMINATION

After the airway and the cardiopulmonary system are supported, efforts should be directed toward removing the toxic substance from the patient (ie, decontamination).[22,40] Decontamination presumes that both the dose and the duration of toxin exposure are important in determining the extent of toxicity and that prevention of continued exposure will decrease toxicity.[29–31,40] This intuitive concept is clearly relevant to ocular, dermal, and respiratory exposures when local tissue damage is the primary problem. Respiratory decontamination involves removing the patient from the toxic environment and providing fresh air or oxygen to the patient. Decontamination of skin and eyes involves flushing the affected area with large volumes of water or saline to physically remove the toxic substance from the surface.[22,23]

Gastrointestinal decontamination

Because most poisonings and overdoses result from oral ingestions, measures to decrease or prevent continued GI absorption have commonly been used to limit the extent of exposure.[22,23,37] GI decontamination should be considered if the ingestion is large enough to produce potentially significant toxicity, or if the potential severity of the ingestion is unknown and the time since ingestion is <1 hour. The following methods have historically been used: (a) evacuation of gastric contents by emesis or gastric lavage, (b) administration of activated charcoal as an adsorbent to bind the toxic substance remaining in the GI tract, (c) use of cathartics or whole-

bowel irrigation (WBI) to increase the rectal elimination of unabsorbed drug, or (d) a combination of any of these methods.[41–46]

The efficacy of GI decontamination varies, depending on when the process is initiated relative to the time of ingestion, dose ingested, and other factors. Furthermore, ipecac-induced emesis, gastric lavage, cathartics, and activated charcoal are not directly associated with improved patient outcomes.[41–46]

The most appropriate method for GI tract decontamination remains unclear because sound comparative data for different methods of GI decontamination are not available. Clinical research in healthy subjects, by necessity, must use nontoxic doses of drugs. Studies using nontoxic doses are not applicable to the overdose situation because alterations in GI absorption can occur with large doses. In addition, low-dose studies generally rely on pharmacokinetic end points such as peak plasma concentrations, area under the plasma concentration–time curve, or quantity of drug recovered from the urine.[41,42,44–46] In contrast, clinical studies of GI decontamination methods in patients who have ingested toxic doses of a substance use clinical outcomes or a directional change in serum drug concentrations.[41,42,45,46] These latter trials are not standardized with respect to the dose ingested or to the time interval between drug ingestion and GI decontamination.[41–46]

Ipecac-Induced Emesis and Gastric Lavage

Ipecac-induced emesis and gastric lavage primarily remove substances from the stomach. Their efficacy is affected significantly by the time the ingested substance remains in the stomach. Gastric lavage and ipecac-induced emesis are most effective when implemented before the substance moves past the stomach into the intestine (usually within 1 hour).[41,42]

The commonly used adult gastric lavage tube (36F) has an internal diameter too small to allow the recovery of large tablet or capsule fragments. An even smaller diameter lavage tube is used for children.[42] Gastric lavage may be useful only if large amounts of a liquid substance were ingested and the patient arrived within 1 hour

of the ingestion.[45] However, patients usually arrive in the ED more than an hour after ingestion, when absorption of the toxin has most likely already occurred. As a result, the efficacy of these procedures in overdose situations is minimal, and no studies have confirmed that use of gastric lavage or ipecac-induced emesis improves the outcome of the patient.[41,42,47] For these reasons, ipecac is no longer used, and gastric lavage is used only in rare, specific situations.

Activated Charcoal

In 1963, a review article concluded that activated charcoal was the most valuable agent available for the treatment of poisoning.[48] This conclusion was based only on studies in fasting patients who had nontoxic exposures. Nevertheless, data from those studies were extrapolated to poisoned patients. Since then, activated charcoal has become the preferred method of GI decontamination for the treatment of toxic ingestions.[22,40,48]

The goal of the therapy is to decrease the absorption of the substance and reduce or prevent systemic toxicity.[43] Unfortunately, there are no satisfactorily designed clinical studies assessing the benefit from the use of activated charcoal to guide the use of this therapy. There is also no evidence that the administration of activated charcoal improves clinical outcomes.[43]

The use of activated charcoal at a dose of 1 g/kg should be considered when the patient has ingested a toxic substance that is known to be absorbed by activated charcoal within 1 hour of the ingestion. The potential for benefit is unknown if the activated charcoal is given >1 hour after ingestion.[43] It should be noted that iron and lithium are not absorbed by activated charcoal. Other forms of GI decontamination must be used to remove those substances from the GI tract.[43]

Generally, the use of activated charcoal is safe. Although there are relatively few reports of adverse effects from the use of activated charcoal, there are numerous reports of complications, usually involving aspiration. It is essential that the patient has an intact or a protected airway (intubation) before activated charcoal is

administered, especially in drowsy patients or in patients who may rapidly become obtunded.[43]

Vomiting with aspiration of activated charcoal occurs in about 5% of patients who receive activated charcoal.[43,49–51] The resulting pulmonary problems can be caused by aspiration of acidic stomach contents or the charcoal. Decreased oxygenation can occur immediately, or pulmonary effects can occur later.[51–55] Acute respiratory distress syndrome has resulted after the unintentional instillation of charcoal into the lung.[51] Aspiration of charcoal can result in chronic lung disease or fatalities, whereas the toxic exposure, for which the charcoal was administered, is often not lethal or even serious.[52,56]

Cathartics

Historically, sorbitol (a cathartic) was often administered with activated charcoal to enhance passage of the charcoal–substance complex through the GI tract. However, decreased transit time through the bowel has not been proved to decrease absorption because drug absorption does not take place in the large bowel.[44] Sorbitol is also associated with vomiting and aspiration.[44] Hypernatremia can also develop subsequent to the administration of repeat doses of activated charcoal with sorbitol.[57,58] Currently, most EDs use aqueous activated charcoal mixtures rather than charcoal–sorbitol combinations. Because cathartics are not effective in reducing drug absorption or increasing patient outcome, their use is no longer advised.[44]

Whole-Bowel Irrigation

WBI with a polyethylene glycol–balanced electrolyte solution (eg, Colyte®, GoLYTELY®) can successfully remove substances from the entire GI tract in a period of several hours. WBI is effective with ingestions of sustained-release dosage forms, as well as with substances that form bezoars (concretions of tablets or capsules), such as ferrous sulfate or phenytoin.[23,45,59] WBI is also indicated when the toxic agent is not adsorbed by activated charcoal (eg, body

packer packets, lithium, iron, potassium).[22,23,45,59] This method of GI decontamination takes much longer to complete and is associated with poor patient compliance because large volumes of fluid (2 L/hour for adults until the effluent is clear) need to be ingested to be effective.[59] A nasogastric (NG) tube can be inserted, and the WBI fluid can be administered via the NG tube so that lack of patient compliance is no longer a factor.[45]

ANTIDOTES AND SPECIFIC TREATMENTS

An antidote is a drug that reverses the toxicity of another substance. Some antidotes can displace a drug from receptor sites (eg, naloxone for opioids, flumazenil for benzodiazepines), and some can inhibit the formation of toxic metabolites (eg, *N*-acetylcysteine [NAC] for acetaminophen, fomepizole for methanol).[23,60,61] Some treatments are highly effective for the management of individual drug overdoses but do not meet the definition of an antidote. For example, sodium bicarbonate is used to treat the cardiotoxicity arising from tricyclic antidepressant (TCA) overdoses, and benzodiazepines are used to treat CNS toxicity associated with cocaine and amphetamine overdoses.[62–64] However, for antidotes to be effective, they must be readily available at the health care facility in adequate doses to treat the patient in a timely manner.[65]

ENHANCING SYSTEMIC CLEARANCE

Hemodialysis and manipulation of urine pH can enhance the clearance of substances. Hemodialysis can successfully treat some specific intoxications (eg, methanol, ethylene glycol, aspirin, theophylline, lithium). Hemodialysis can also be used in patients with severe acid–base disturbances or renal dysfunction.[47] Alkalinization of the urine can enhance the elimination of drugs such as aspirin and phenobarbital.[66–68]

MONITORING OUTCOME

Selecting the appropriate parameters and length of time to monitor a patient who has been exposed to a toxic agent requires knowledge

of toxic effects and the time course of the intoxication.[33,34] Most patients who are at risk for moderate or severe toxicity should be monitored in an intensive care unit (ICU) with assessments of cardiac, pulmonary, and CNS function.[69,70]

ASSESSMENT OF SALICYLATE INGESTION

Gathering a History

CASE 5-1

QUESTION 1: A.J., the mother of a 3-year-old child, states that her son, R.J., has ingested some aspirin tablets.

What additional information should be obtained from or given to A.J. at this time?

Obtaining an initial assessment of the patient's status is essential. The caller's telephone number should be obtained in the event that the call is disconnected, initial recommendations need to be modified, or subsequent follow-up is needed. The health care provider should ask for patient-specific information with questions that are nonthreatening and nonjudgmental. The caller should be reassured that calling for help was the right thing to do.

Evaluating Clinical Presentation

CASE 5-1, QUESTION 2: On further questioning, A.J. states that R.J. is crying and has a stomachache. Otherwise, the child is acting normally. R.J. was found sitting on the bedroom floor with an aspirin bottle in his hand and some partially chewed tablets on the floor next to him. A.J. states that the child had the same look on his face that he has when he eats things that he does not like. A.J. reports that she can see white tablet material on the child's teeth. The mother was gone no more than 5 minutes and had asked her 6-year-old son to watch his brother. What additional information is needed to correctly assess the potential for toxicity in R.J.?

To determine the potential toxicity of an unintentional ingestion, it is important to assess the presence of symptoms and to identify the substance ingested. Inquiries should begin with open-ended questions to determine the facts that the caller is certain of versus what may have been assumed. The answers usually point to more specific information that is needed to accurately assess the exposure.[20]

R.J.'s symptoms presently are not life-threatening. His behavior is consistent with being scared in response to the mother's anxiety. Once it has been established that the child does not need immediate life-saving treatment, the caller is generally able to answer additional questions.

A.J. has already provided information about the child's symptoms. More information is needed to determine the identity of the ingested substance, the time of ingestion, the brand of aspirin (to ensure that the product is not an aspirin-combination or even an aspirin-free formulation), the dosage form, the number of dosage units in a full container, and the number of remaining dosage units in the container. The parent should be advised to look for tablets under beds, rugs, or other locations out of sight (eg, wastepaper baskets, toilets, pet food dishes, pockets). The dosage forms in the container should be identical in appearance, and the contents should be what are stated on the label. Information concerning the child's weight and health status, as well as whether the child is taking other medications, is also important. The child's weight is useful in determining the maximum milligram per kilogram dose of aspirin that was ingested.

When more than one child is present during an ingestion, the caller should be questioned as to whether other children also could have participated in the ingestion. In this situation, the children could have shared equally in the missing medication, all of the drug could have been fed to one child, or all of the drug could have been ingested by the oldest or most aggressive child. When it is unclear how much is missing among a group of children, each child should be evaluated and managed as if he or she may have ingested the total missing quantity.

Triage of Call

Case 5-1, Question 3: A.J. has now determined that a total of seven tablets, each containing 81 mg per tablet of aspirin, are missing from the bottle. Because A.J. recalls having taken two aspirin tablets from this bottle, it is not likely that her son took more than seven tablets. A.J. states that R.J. weighs 41.88 pounds (19 kg). What treatment is needed for this child?

The maximal dose of aspirin ingested by this child is likely to be much less than the minimal dose required to cause significant symptoms based on his weight for his age (ie, ~41.88 pounds [19 kg]). A dose of 150 mg/kg of aspirin is the smallest dose at which treatment or assessment at a health care facility is necessary.[68,71] A.J. is likely to have ingested a maximum of 567 mg of aspirin (ie, seven 81-mg tablets), which is about 29.8 mg/kg (567 mg divided by 41.88 pounds [19 kg]). If this child is healthy, takes no medications, and is not allergic to aspirin, the child does not require any treatment. With this history of ingestion, the only adverse effect that might occur is some mild nausea. Providing information to the mother that her child had not ingested a toxic or dangerous amount will be reassuring.

For many years, aspirin was the most common cause of unintentional poisoning and poisoning deaths among children.[71–73] However, safety closure packaging and reduction of the total aspirin content in a full bottle of children's aspirin to ~3 g has steadily reduced the frequency of pediatric aspirin poisoning and deaths.[72–74] Although acute aspirin poisoning remains a problem, the largest percentage of life-threatening intoxications now results from therapeutic overdose.[68] Therapeutic overdoses occur when a dose is given too frequently, when both parents unknowingly dose the child with the drug, or when too large a dose is given. Therapeutic overdoses are especially problematic when excessive doses are given for a prolonged period and the drug is able to accumulate.[68]

Patient Outcome

Follow-up telephone consultation on toxic ingestions is important to identify children who unexpectedly develop symptoms that might need to be treated. A telephone call to A.J. 6 to 24 hours after her initial call would be appropriate to follow up on the child. On a call back to A.J., she stated that she gave R.J. lunch at the appropriate usual time. R.J. then watched cartoons, took his usual nap, and remained asymptomatic.

Acute and Chronic Salicylism

SIGNS AND SYMPTOMS

CASE 5-2

QUESTION 1: A.S., a 71-year-old, 130.07-pound (59-kg) female with a history of chronic headaches, has taken 10 to 12 aspirin tablets daily for several months. On the evening of admission, she became lethargic, disoriented, and combative. Additional history revealed that she ingested up to 95 aspirin tablets on the morning of admission (about 11 hours earlier) in a suicide attempt. She reported ringing in her ears, nausea, and two episodes of vomiting. She is disoriented and lethargic. Vital signs were BP 148/95 mm Hg, pulse 114 beats/minute, respirations 38 breaths/minute, and temperature 101.2 °F (38.44 °C). A.S.'s laboratory data obtained on admission were as follows:

Serum sodium (Na), 144 mEq/L
Potassium (K^+), 2.5 mEq/L
Chloride (Cl^-), 103 mEq/L
Bicarbonate, 9 mEq/L
Glucose, 58 mg/dL
Blood urea nitrogen (BUN), 38 mg/dL
Creatinine, 2.5 mg/dL

Arterial blood gas (ABG) values (room air) were as follows: pH, 7.14; P_{CO_2}, 18 mm Hg; and P_{O_2}, 96 mm Hg. A serum salicylate concentration measured ~12 hours after the acute ingestion was 90 mg/dL. Her hemoglobin was 9.6 g/dL, with a hematocrit of 28.9% and a prothrombin time (PT) of 16.4 seconds.

Is A.S. at high risk because of her ingestion?

The symptoms and severity of salicylate intoxication depend on the dose consumed; the patient's age; and whether the ingestion

was acute, chronic, or a combination of the two.[73,75,76] This case illustrates an acute ingestion in someone who has also chronically ingested aspirin. Acute ingestion of 150 to 300 mg/kg of aspirin is likely to produce mild-to-moderate intoxication, >300 mg/kg indicates severe poisoning, and >500 mg/kg is potentially lethal.[68,71] A.S., who ingested ~523 mg/kg, has taken a potentially lethal dose. Chronic salicylate intoxication is usually associated with ingestion of >100 mg/kg/day for >2 days.[68,71] A.S. has been taking 66 mg/kg/day for her headaches in addition to her acute ingestion. A.S. demonstrates many of the findings typical of severe acute salicylism (see sections on Pathophysiology of Salicylate Intoxication and Assessment of Toxicity). A.S.'s prognosis is potentially poor because she is elderly and has taken a potentially lethal overdose of aspirin.

Pathophysiology of Salicylate Intoxication

Case 5-2, Question 2: What are the pathophysiological and clinical features of acute and chronic salicylism?

Toxicity from salicylate exposure results in direct irritation of the GI tract, direct stimulation of the CNS respiratory center, stimulation of the metabolic rate, lipid and carbohydrate metabolism disturbances, and interference with hemostasis.[68,71,73,75,76] Toxic doses of salicylate directly stimulate the medullary respiratory center, leading to nausea, vomiting, tinnitus, delirium, tachypnea, seizures, and coma and influence several key metabolic pathways.[68,73–77] Direct stimulation of the respiratory drive increases the rate and depth of ventilation, which can result in primary respiratory alkalosis. The respiratory alkalosis causes increased renal excretion of bicarbonate, resulting in decreased buffering capacity. The patient usually presents with a partially compensated respiratory alkalosis.[68,74,75,77] Hypokalemia can result from increased GI and renal losses of potassium, as well as from systemic alkalosis.[68,75,76] Although marked metabolic and neurologic abnormalities are most commonly observed in young children with advanced salicylate intoxication, adolescents or adults

acutely poisoned with a large dose of salicylates can exhibit these symptoms as well.[68,74,75] Acute salicylism in a young child often takes a more severe course than that typically seen in adults. After acute ingestion, children quickly pass through the phase of pure respiratory alkalosis. Renal bicarbonate loss secondary to respiratory alkalosis reduces the buffering capacity more profoundly in a child and facilitates the development of metabolic acidosis.[68,73,75,77]

Salicylates have toxic effects on several biochemical pathways that contribute to metabolic acidosis and other symptoms.[68,75,77] Mitochondrial oxidative phosphorylation is uncoupled and results in an impaired ability to generate high-energy phosphates, increased oxygen use and carbon dioxide production, increased heat production and hyperpyrexia, increased tissue glycolysis, and increased peripheral demand for glucose. Salicylates also inhibit key dehydrogenase enzymes within the Krebs cycle, resulting in increased levels of pyruvate and lactate. The increased demand for peripheral glucose causes increased glycogenolysis, gluconeogenesis, lipolysis, and free fatty acid metabolism. The latter results in enhanced formation of keto acids and ketoacidosis.[73,77]

The patient may become severely volume depleted through several mechanisms.[68,75,77] Hyperthermia and hyperventilation produce increased insensible water loss, vomiting may promote GI fluid losses, and the solute load caused by altered glucose metabolism results in osmotic diuresis. Depending on the patient's acid–base balance and net fluid and electrolyte intake and output, serum sodium and potassium concentrations may be normal, elevated, or decreased. Hypernatremia and hypokalemia are most common.[73,75]

Blood glucose concentration is usually normal or slightly elevated, although hypoglycemia may accompany chronic salicylism (eg, as illustrated by A.S.) or occur late in acute intoxication. CNS glucose levels can be markedly reduced in the presence of normal blood glucose concentrations because increased CNS glucose utilization to generate high-energy phosphate exceeds the rate at which glucose can be supplied.[68,73,75,77]

ASSESSMENT OF TOXICITY

CASE 5-2, QUESTION 3: What signs, symptoms, and laboratory values in A.S. are consistent with salicylate intoxication?

A.S. demonstrates many of the findings typical of severe acute salicylism. Hyperventilation has resulted from the direct respiratory stimulant effects of salicylate and as compensation for her metabolic acidosis (P_{CO_2}, 18 mm Hg; pH, 7.14; serum bicarbonate, 9 mEq/L; respiratory rate, 38 breaths/minute). Hypokalemia (2.8 mEq/L) in the presence of metabolic acidosis represents severe potassium depletion because of increased renal and, possibly, GI losses. Hyperpyrexia caused by salicylate is present in A.S., although an infectious cause must also be considered. Her neurologic symptoms of lethargy, disorientation, and combativeness, as well as tinnitus, nausea, and vomiting, are commonly seen in severe salicylate intoxication. In addition, being elderly and taking a lethal amount of aspirin bodes ill for this patient's outcome.

LABORATORY EVALUATION

CASE 5-2, QUESTION 4: What objective evaluations should be assessed in a patient with presumed salicylate intoxication?

A.S.'s workup illustrates a thorough initial patient evaluation. Laboratory evaluation should include ABG values, serum electrolytes, BUN, serum creatinine, blood glucose, and a complete blood cell count.[73,74] Urine should be tested for specific gravity and pH.[73] In symptomatic patients, a PT or an international normalized ratio (INR) and partial thromboplastin time are useful to assess the presence of salicylate-induced coagulopathy. Vitals signs should be monitored for an increased respiratory rate and hyperpyrexia.[74,75] Physical examination should include an evaluation of chest radiograph, cardiopulmonary and neurologic function, and measurement of urine output.[75]

A salicylate blood concentration should be obtained immediately and every 2 hours in patients.[24,64,73,75] Serum salicylate concentrations should be reassessed every 2 hours to verify that the original concentration represented a peak level and that the salicylate level is decreasing rather than increasing.[24,68,73,76,78] Obtaining the units of measurement on salicylate serum concentrations is essential because different laboratories report concentrations in different units (eg, mg/dL, µg/mL, mmol/L). An incorrect interpretation of the salicylate unit of measurement can result in overestimates or underestimates of the severity.[24]

Manifestations of severe acute salicylism include a variety of neurologic signs and symptoms: disorientation, irritability, hallucinations, lethargy, stupor, coma, and seizures.[69,73] Hyperthermia may be marked and can result in the inappropriate administration of aspirin as an antipyretic. Coagulopathy can occur because of impaired platelet function, hypoprothrombinemia, reduced factor VII production, and increased capillary fragility, especially when aspirin is taken chronically.[75–77] Pulmonary edema and acute renal failure also can occur, but the former occurs more commonly after chronic intoxication.[75,77,78]

Chronic salicylism symptoms are similar to that of acute intoxications. However, patients with chronic exposures may have fewer GI symptoms, but they generally appear more ill and have more CNS symptoms.[71,79] In both adults and children, the principal signs of chronic salicylism are a partially compensated metabolic acidosis, increased anion gap, ketosis, dehydration, electrolyte loss, hyperventilation, tremors, agitation, confusion, stupor, memory deficits, renal failure, and seizures.[73,75,76,80] The severity of CNS manifestations is related to the cerebrospinal fluid (CSF) salicylate concentration.[74,75] CSF concentrations may increase in the presence of systemic acidosis because a greater fraction of salicylate is not ionized and can cross the blood–brain barrier. Therefore, metabolic acidosis is especially dangerous in a salicylate-intoxicated patient.[73,75]

Unless the history of salicylate intake is specifically sought, the problem may not be immediately apparent, especially in the elderly

in whom such findings are likely to be attributed to other causes (eg, encephalitis, meningitis, diabetic ketoacidosis, myocardial infarction).[24,75,79] Delay in diagnosis has been associated with increased mortality.[24,68,75,79] Unfortunately, plasma salicylate concentrations do not correlate well with the degree of poisoning in chronically intoxicated patients. It is more important to treat the patient according to the clinical status rather than according to his or her salicylate concentration.[71] Death in patients with salicylism, whether acute or chronic, results from CNS or cardiac dysfunction, or pulmonary edema.[73,75,79]

MANAGEMENT

Case 5-2, Question 5: What would be a reasonable management plan for A.S.?

Management of salicylate intoxication depends on the degree of acid–base and electrolyte disturbances.[68,73,75] Activated charcoal is not indicated for A.S. because the ingestion occurred ~10 hours ago and she has a somewhat altered mental status.[46] The risk of aspiration is greater than the value of possibly adsorbing any remaining aspirin from the GI tract. In addition, A.S. already has symptoms of salicylate poisoning, indicating that the aspirin has been absorbed. Others might argue that if she ingested 95 tablets, some of the drug may still be present in the GI tract and giving activated charcoal late may bind some of the drug still present. The benefit versus risk of giving activated charcoal must be assessed. A.S.'s hypokalemia, acidosis, and hypoglycemia must be corrected, and it is probably best accomplished through the administration of intravenous (IV) hypotonic saline–dextrose solutions combined with potassium supplementation. This solution is administered at a rate that replaces the patient's deficits and keeps pace with continued losses.[68,73,75–77] Care should be taken to avoid overzealous fluid therapy, which can predispose the patient to cerebral or pulmonary

edema.[73,77] Administration of an IV dextrose bolus is also indicated because A.S. is hypoglycemic (60 mg/dL).[73,75–77]

Sodium bicarbonate

It is important to correct A.S.'s acidosis because acidosis will increase CSF salicylate concentrations.[74,75] Correction of acidosis can be accomplished by adding sodium bicarbonate to her IV fluids.[68,73–76] A.S.'s serum sodium and potassium concentrations should be monitored closely because adding potassium to IV fluids will mostly likely be required.[81] Providing adequate ventilation to prevent respiratory alkalosis is essential. With a respiratory rate of 36 breaths/minute, placing the patient on a ventilator to assist with breathing might be considered. However, forced mechanical ventilation can interfere with the patient's need to compensate to maintain the serum pH. Patients on ventilators can become severely acidotic, which can result in death because of an inability to compensate adequately.[73,82]

Seizures

Seizures are not evident in A.S. but can be encountered in cases of severe salicylate poisoning. Seizures generally carry a poor prognosis and are indicative of severe salicylate intoxication that requires hemodialysis.[73] Other treatable causes of seizures (eg, marked alkalosis, hypoglycemia, hyponatremia) can be present in individuals such as A.S. and should be ruled out. If seizures occur, benzodiazepines are the drugs of choice for treatment.[73]

Coagulopathy and hyperthermia

Coagulopathy generally responds to vitamin K_1, which should be given if the PT or INR is prolonged.[73] GI bleeding or other hemorrhage can occur, but it is not common.[73,75,76] Mild hyperthermia usually does not require therapy, but cooling fans and mist may be required for extremely elevated temperatures.[73,77]

Pulmonary edema

Noncardiogenic pulmonary edema commonly occurs in salicylate intoxications, especially when the overdose is attributable to chronic ingestions.[73,75,78] Pulmonary edema is associated with a high incidence of neurologic symptoms in patients and can occur even without fluid overload.[75,78] Increased alveolar capillary membrane permeability, prostaglandin effects, and a metabolic interaction with platelets that release membrane permeability substances are the primary mechanisms for the cause of pulmonary edema associated with salicylate overdose. Treatment is aimed at reducing salicylate levels via alkalinization or hemodialysis.[78]

Alkalinization

Case 5-2, Question 6: What measures will enhance salicylate elimination? Which of these may be indicated in A.S.?

Alkalinization of the urine and hemodialysis can enhance the excretion of salicylate in overdose situations.[68,74] Hemodialysis is preferred because it can also correct fluid and electrolyte imbalances.[75,78,79] Sodium bicarbonate is recommended for alkalinization to increase the arterial pH with the goal of minimizing salicylate transport into the CNS.[74,75,77]

Although large doses of sodium bicarbonate can enhance the renal elimination of the weak acid and shorten its half-life, this treatment does not favorably influence the morbidity or mortality of patients with salicylism. Alkalinization with forced fluid diuresis can also place the patient at risk for sodium and fluid retention, as well as pulmonary edema if too much fluid is given too quickly.[76,78–83] Whether the urine can be adequately alkalinized (pH > 7) in severely intoxicated pediatric patients has been questioned because of the large acid load that is excreted.[68,73,74] Nevertheless, urine alkalinization with sodium bicarbonate should be attempted in severely salicylate-intoxicated adult patients such as A.S.

Potassium replacement in patients receiving alkalinization is essential.[73,75,77] These patients may require large amounts of potassium supplementation as a result of renal wasting of potassium. The risk of pulmonary edema can be minimized if this is done without forcing fluids.[73,75–77]

Hemodialysis should be considered in patients who show progression of severe salicylate intoxication and seizure activity, renal failure, or plasma salicylate concentrations in the potentially fatal range.[68,75,76,78,80] Patients with a chronic exposure, acidosis, or CNS symptoms and those who are elderly or ill are at high risk and should be considered for early dialysis.[75,80] Because A.S. has many of the risk factors, she is a candidate for emergent hemodialysis.

CLINICAL OUTCOME

A repeat salicylate level 6 hours later (18 hours after ingestion) had increased to 95 mg/dL. Her chemistry panel revealed serum sodium, 143 mEq/L; potassium, 2.2 mEq/L; chloride, 99 mEq/L; bicarbonate, 8 mEq/L; glucose, 77 mg/dL; creatinine, 4.9 mg/dL; and BUN, 43 mg/dL. Her hemoglobin was 8.4 g/dL, with a hematocrit of 23% and a PT of 16.6 seconds. A.S.'s pH on blood gases remained in the 7.2 to 7.3 range. Urinary alkalinization was attempted with a high-dose IV sodium bicarbonate infusion in an attempt to reach a urine pH of 7.5. However, her urine pH never increased above pH 5.7. A.S. became fluid overloaded and exhibited dyspnea. She was placed on a ventilator with worsening of her symptoms. A chest radiograph showed pulmonary edema. A.S. became confused and agitated, pulling at her IV lines and trying to get out of bed. Nephrology was consulted to provide emergent hemodialysis to correct the acidosis, electrolyte abnormalities, and fluid overload. As the catheter was being placed, the patient had a tonic-clonic seizure. Lorazepam 2 mg IV was administered, and the seizure stopped. At this time, the patient was unresponsive. She had another tonic-clonic seizure, went into respiratory arrest, and was coded, but could not be resuscitated.

ASSESSMENT OF IRON INGESTION

Gathering History and Communications

CASE 5-3

QUESTION 1: The babysitter of K.M., a 21-month-old female, calls the ED because the child is vomiting and appears to have been playing with an open, unlabeled bottle of green tablets. The child was left alone in her room for about 20 minutes to take a nap.

Why might the consultation with this babysitter be expected to be more difficult than was the consultation in Case 5-1, Question 1?

In cases of unintentional pediatric ingestions, phone calls to a health care provider, a health care facility, or a poison control center made by individuals other than the parent are usually more difficult to manage because the caller is often unable to provide all patient-specific information needed (eg, patient weight, chronic medications) to accurately assess the drug ingestion. Additional information is often needed from a parent. Nonparent callers also tend to be more upset about an unintentional ingestion and may have more difficulty than a parent in taking decisive action.

Triage of Call

CASE 5-3, QUESTION 2: Despite additional questioning, K.M.'s babysitter cannot identify the tablets. K.M. is still vomiting; and the vomitus is green, similar to the color of the tablets. According to the babysitter, K.M. is the child of a single mother who is not known to have flu or any GI illness at this time. The child's mother is currently at work and is not answering her cell phone. What recommendations could be provided to K.M.'s babysitter at this time?

With this history, the practitioner should consider whether the information presented by K.M.'s babysitter is consistent with a drug ingestion and whether this incident is likely to be associated with a

significant adverse outcome. Most 2-year-old children experience limited toxicity with unintentional drug ingestions because the amount of substance actually ingested is usually small.[5,6] Nevertheless, some substances (eg, methanol, ethylene glycol, nicotine, caustic substances, camphor, chloroquine, clonidine, diphenoxylate-atropine, theophylline, oral hypoglycemic agents, calcium channel blockers, TCAs, opioids) can produce significant toxicity even when small amounts are ingested.[6,84,85]

Although the history of drug ingestion in K.M. is somewhat vague, the description of green tablets and green-colored vomitus suggests possible ingestion of iron tablets. Because this is a possible exposure with a realistic potential for severe toxicity, K.M. should be brought to the ED for evaluation. Depending on the distance to the hospital and the anxiety level of the babysitter, the practitioner might want to instruct the babysitter to call for an ambulance. She should be instructed to bring the green tablets to the ED along with the child so that the tablets can be identified. Other medications in the house should also be brought to the ED, and the mother should be contacted.

Substance Identification

Case 5-3, Question 3: K.M.'s mother was reached and confirmed that the only green tablets in the house are her iron supplements. The babysitter was instructed to bring K.M. to the nearest ED, and the mother will meet them there. On arrival, K.M. is still vomiting but is fully awake and alert, with a heart rate of 122 beats/minute, a respiratory rate of 26 breaths/minute, a rectal temperature of 98.9 °F (37.17 °C), and pulse oximetry of 100%. How can the maximal potential severity of this ingestion be estimated at this time?

K.M.'s vital signs, when corrected for age, are normal. Attention should now focus on identifying the ingested substance and the maximal potential severity of the ingestion. Although this case involves an unknown ingestion, with a possibility of being a severe case of iron intoxication, the identity of the tablets still has not been

verified. Therefore, K.M. must be carefully assessed, and the ingestion history reaffirmed.

All solid dosage prescription drugs are required by the U.S. Food and Drug Administration (FDA) to have identification markings. Online Resources (eg, *Facts and Comparisons*,[86] *Prescriber's Digital Reference*[87]), computerized databases (eg, Micromedex),[88] and the product manufacturers can assist in identifying solid dosage forms. Websites such as http://www.rxlist.com[89] and http://www.drugs.com[90] can also be useful in obtaining drug identification information.

The imprint code markings on the green tablet brought to the ED with K.M. and the mother's assistance should be sufficient to correctly identify the medication. Once the tablet has been identified, the maximal number of tablets ingested should be estimated.

In K.M.'s case, the bottle containing the green tablets was unlabeled. In most cases, the label on the medication container can provide information on the identity and number of tablets dispensed. The date the prescription was obtained, the number of estimated doses taken, and the number currently remaining in the medication container can be used to approximate the maximal number of tablets ingested.

K.M.'s vital signs and symptoms should be monitored closely to evaluate whether her clinical status is consistent with expectations based on the suspected ingestion. Nausea, vomiting, diarrhea, and abdominal pain are common early signs of iron intoxication.[91–96] The absence of symptoms, especially within a short time of the presumed ingestion, should not be interpreted as an indication that a poisoning has not occurred.[91,93–96]

Evaluating Severity of Toxicity

Case 5-3, Question 4: K.M. weighs 24.25 pounds (11 kg), appears to be in no distress, and has stopped vomiting. About 25 mL of dark-colored vomitus was recovered, but no tablets are found. The vomitus tested negative for blood. A maximum of seven tablets was ingested based on the mother's recall. What degree of toxicity should be expected in K.M.?

The potential severity of toxicity can be estimated for commonly ingested drugs such as acetaminophen,[97] salicylates,[71] iron,[91] and TCAs[98] because of well-established dose–toxicity relationships. Acute elemental iron ingestions of <20 mg/kg are usually nontoxic, doses of 20 to 60 mg/kg result in mild-to-moderate toxicity, and doses >60 mg/kg are potentially fatal.[92,94,96]

The independent verification of the tablet by K.M.'s mother and the tablet imprint indicate that each tablet contained 325 mg of ferrous fumarate in an enteric-coated formulation. Because the dose–toxicity relationship of iron is based on the amount of elemental iron ingested, knowledge of the specific iron salt is important in calculating the ingested dose. Ferrous fumarate contains 33% elemental iron, whereas ferrous gluconate contains 12%, and ferrous sulfate contains 20%.[91,92,94,95] Therefore, each 325-mg ferrous sulfate tablet contains 108 mg of elemental iron. K.M. ingested a maximum of seven enteric-coated ferrous fumarate 325-mg tablets, and she weighs 24.25 pounds (11 kg). Her ingestion of ~69 mg/kg (108 mg per tablet × 7 tablets = 756 mg total ÷ 24.25-pound [11-kg] patient weight) of iron places her at risk for severe toxicity. Although K.M.'s only symptom is vomiting at this time, absorption could be delayed because she ingested an enteric-coated formulation.

Abdominal Radiographs

Case 5-3, Question 5: K.M. is expected to experience potentially severe toxicity from her iron ingestion. Why would an abdominal radiograph be useful to verify the number of iron tablets ingested?

In theory, radiopaque substances (eg, iron, enteric-coated tablets, chloral hydrate, phenothiazines, heavy metals) can be visualized in the GI tract by an abdominal radiograph.[99] The ability of a radiograph to detect the presence of a radiodense substance depends on the dosage form, concentration, and molecular weight of the substance. The intact dosage form can often be detected if the tablet has not already disintegrated or dissolved.[99]

Less than one-third of pediatric abdominal radiographs show positive evidence of tablets or granules after iron poisoning.[100] Children are more likely than are adults to chew tablets rather than swallow them whole, and false-negative results can occur when whole tablets have not started to disintegrate. If the tablets were chewed, an abdominal radiograph is not likely to be useful for verifying the number of iron tablets ingested. However, an abdominal radiograph after the completion of GI decontamination can help assess whether additional decontamination is needed.[99]

Gastrointestinal Decontamination

Case 5-3, Question 6: Would gastric lavage or activated charcoal not be indicated for the management of K.M.'s iron ingestion? Why or why not?

When selecting a method of GI decontamination, consider the substance ingested, maximal potential toxicity expected from the drug dosage form, potential time course of toxicity, time elapsed between ingestion and the initiation of treatment, symptoms, and physical examination findings. Decontamination with activated charcoal is not indicated in K.M. because iron tablets are not adsorbed by activated charcoal.[49,91,99] Gastric lavage would also be ineffective because the removal of large undissolved iron tablets from the stomach is limited by the small internal diameter of the gastric lavage tube, especially in pediatric patients.[99,100]

Whole-Bowel Irrigation

Case 5-3, Question 7: What other method of GI decontamination should be considered for K.M.?

WBI with a polyethylene glycol electrolyte solution can be considered in this case. WBI fluid can be administered orally or by an NG tube at a rate of 1.5 to 2 L/hour for adults and at a rate of 500

mL/hour for children.[59,101] Although the ingestion of a large volume of fluid over several hours and the likelihood of nausea and vomiting often result in poor patient compliance, K.M. is hospitalized and the fluid can be infused by an NG tube. WBI should be continued until the rectal effluent is clear, which can take many hours.[59,101,102]

MONITORING EFFECTIVENESS OF TREATMENT

Case 5-3, Question 8: How should the effectiveness of GI decontamination be assessed in the ED?

To assess the effectiveness of GI decontamination, the return fluid from the WBI is visually inspected for tablets or tablet fragments. Increasing serum iron concentrations, deteriorating clinical status, or evidence of radiodense tablets in the GI tract on abdominal radiograph are all indications for more aggressive treatment.[92,94,102]

Serum Iron Concentrations

Case 5-3, Question 9: At this time, K.M. does not appear to be experiencing any CNS or cardiovascular symptoms associated with toxic iron ingestions. She did have one episode of diarrhea that tested negative for blood. A serum iron concentration, obtained about 4 hours after the ingestion, was 480 µg/dL (normal, 60–160 µg/dL). What conclusions as to severity or likely clinical outcome can be derived from this serum iron concentration?

The serum iron concentration provides an indication as to whether more aggressive therapy is needed.[96,100,103] The higher than normal serum iron concentration confirms the suspicion that K.M. has ingested iron tablets despite both her current lack of serious symptoms and the absence of tablet evidence in the rectal effluent or by abdominal radiograph.

The time course of absorption is probably the most difficult pharmacokinetic parameter to evaluate with toxic ingestions. Drug concentrations can continue to rise after an overdose despite GI

decontamination.[93,95,96,103] This prolongation of absorption time is further complicated when sustained-release or enteric-coated dosage formulations have been ingested because the onset of symptoms is unpredictable.[94]

K.M.'s serum iron concentration of 480 µg/dL suggests a serious ingestion because peak serum iron concentrations >500 µg/dL are usually predictive of significant toxicity.[93–96,100,103] This single serum iron concentration does not provide information as to whether the serum concentration is rising or declining or when the serum iron concentration will peak as a result of her iron ingestion.[104] Iron tablets may also clump together and form a bezoar, which can result in prolonged absorption and delay the onset of toxicity.[93,96] Samples for peak serum iron concentration should be obtained 4 to 6 hours after ingestion.[94–96,103] Although K.M.'s serum iron concentration was measured ~3 hours after ingestion, another serum iron level is needed in 2 to 4 hours because she ingested an enteric-coated formulation.

Blood Glucose, White Blood Cell Count, and Total Iron–Binding Capacity

Case 5-3, Question 10: K.M. was administered WBI through the NG tube for several hours until the rectal effluent was clear. At this time, K.M. had three more episodes of vomiting and became drowsy and fussy. A repeat serum iron concentration was ordered at 6 hours after ingestion. What other laboratory tests could be helpful in assessing the potential toxicity of iron in K.M.?

Blood glucose concentrations and white blood cell (WBC) counts usually are increased when serum iron concentrations are >300 µg/dL. A WBC count >15,000/mL and a blood glucose concentration >150 mg/dL within 6 hours of ingestion generally suggest a higher likelihood of severe toxicity.[93] These tests provide supplemental confirmation of iron intoxication and may be useful in medical facilities in which serum iron concentrations cannot be obtained. These laboratory tests are not routinely monitored in iron poisoning

because of the poor sensitivity (about 50%).[94] Treatment should not be based on a WBC and glucose concentration alone.[93–95,100] If a patient with severe iron toxicity presents to a health care facility that cannot perform timely serum iron levels, either the blood iron sample must be sent to a laboratory that can do the testing quickly or the patient must be transferred to a health care facility that can do serum iron testing for patient monitoring.

It was once believed that if the serum iron concentration exceeded the total iron–binding capacity concentration, it would indicate substantial iron toxicity. However, this theory has not held up, and the total iron–binding capacity test is no longer used to monitor iron toxicity.[99]

Stages of Iron Toxicity

Case 5-3, Question 11: It is now 6 hours since K.M. ingested the iron tablets. Her second serum iron concentration is not yet available. She continues to be drowsy and fussy, and she has missed her usual nap. She is still vomiting. Why is K.M.'s relatively mild course at this time not particularly reassuring?

The time between the ingestion of an overdose of drugs and the development of severe toxicity can be delayed. It is unclear why there may be an asymptomatic period, but it may be secondary to delayed absorption of the ingested drug, the time required for the drug distribution, or the time needed to form a toxic metabolite. Consequently, K.M. may still exhibit further symptoms of severe toxicity. Four distinct stages of symptoms can be encountered with iron toxicity.[91–96]

STAGE I

Stage I symptoms usually take place within 6 hours of ingestion, during which nausea, vomiting, diarrhea, and abdominal pain occur, probably secondary to the erosive effects of iron on the GI mucosa. The caustic effects of free iron can cause bleeding, as evidenced by

blood in the vomitus and stool. In more severe intoxications, CNS and cardiovascular toxicity can be present during stage I.[93–96]

STAGE II

The second stage of iron toxicity has been suggested as a period of reduced symptoms and an apparent clinical improvement. This stage can last for up to 12 to 24 hours after the ingestion and could be misinterpreted as resolving toxicity. This stage may represent the time needed for the absorbed iron to distribute throughout the body before systemic symptoms develop.[91] In most severe cases, stage II does not occur and the patient's condition continues to deteriorate.[93–96]

STAGE III

Stage III generally occurs 12 to 48 hours after iron ingestion and is characterized by CNS toxicity (eg, lethargy, coma, seizures) and cardiovascular toxicity (eg, hypotension, shock, pulmonary edema). Metabolic acidosis, hypoglycemia, hepatic necrosis, renal damage, and coagulopathy can also happen during this stage.[93–96]

STAGE IV

The final stage is apparent 4 to 6 weeks after acute iron ingestion and consists of delayed-onset GI tract sequelae secondary to the initial local toxicity. In this stage, prior tissue damage can progress to gastric scarring and strictures at the pylorus, resulting in permanent abnormalities of GI function.[93–96]

Patients can present to the health care facility in any stage of iron toxicity and can have a fatal outcome in any stage. Determination of a stage of toxicity should be based on clinical symptoms rather than time of ingestion.[95]

Deferoxamine Chelation

CASE 5-3, QUESTION 12: The second serum iron concentration that was obtained 6 hours after ingestion has increased from 480 to 560 µg/dL. The child has continued to vomit and appears pale. What criteria are most important in determining whether K.M. is a candidate for the antidote deferoxamine?

Deferoxamine (Desferal®) chelates iron by binding ferric ions in plasma to form the iron complex ferrioxamine.[94] Deferoxamine prevents iron toxicity at a cellular level by removing iron from mitochondria.[92] Unfortunately, deferoxamine is not a very effective antidote because a relatively small amount of iron is bound (~9 mg of iron to 100 mg of deferoxamine).[104,105] The iron–deferoxamine complex is primarily excreted renally as ferrioxamine.[92,94,95] Renal elimination of the ferrioxamine usually results in pinkish orange urine, often described as "vin rosé."[92,94,95] Deferoxamine therapy should be initiated when serum iron concentrations exceed 500 µg/dL and when symptoms of iron toxicity (eg, GI symptoms, hemorrhage, coma, shock, seizures) are present.[92–95] K.M. is experiencing symptoms, she presumably ingested up to 69 mg/kg of elemental iron, and iron absorption appears to be ongoing based on the increase in her serum iron concentration. Therefore, K.M. should be treated with deferoxamine.

DEFEROXAMINE DOSE

CASE 5-3, QUESTION 13: What dose of deferoxamine should be prescribed for K.M., and how should it be administered?

Deferoxamine is most effective when administered as a continuous IV infusion because of its short half-life (76 ± 10 minutes).[95,104] Clinically, a slow IV infusion is preferred over intramuscular (IM) administration because the IV dose is better controlled, less painful, and better absorbed than is an IM dose.[95,96] Deferoxamine is usually administered in a continuous IV infusion at a dose of 15 mg/kg/hour. However, doses up to 45 mg/kg/hour have been used in patients with severe iron poisoning.[93–96,104]

Administering IV boluses of deferoxamine too rapidly can result in hypotension.[94,96,104,105] According to the manufacturer, the total deferoxamine dose should not exceed 6 g every 24 hours in children or adults, but adverse effects have not been seen in patients who received >6 g every 24 hours.[105]

Deferoxamine therapy should be initiated in K.M. at a lower rate of about 8 mg/kg/hour, and her clinical status should be monitored closely. If the dose is tolerated, the rate can be increased every 5 minutes until the desired rate of 15 mg/kg/hour is reached.[90]

MONITORING AND DISCONTINUATION

Case 5-3, Question 14: K.M. is admitted to the pediatric ICU shortly after the initiation of a deferoxamine infusion at 8 mg/kg/hour. How should deferoxamine therapy be monitored, and when should it be discontinued?

The rate of deferoxamine infusion should be increased with symptoms of severe iron toxicity and decreased if patients experience adverse effects.[93,94,96,105] Treatment should continue until the serum iron concentration is <100 µg/dL and symptoms of iron toxicity resolve.[105] Patients usually require chelation therapy for about 1 to 2 days, depending on the severity of symptoms.[93–95] Unnecessarily prolonged chelation therapy should be avoided because deferoxamine infusion for >24 hours has been associated with the development of acute respiratory distress syndrome.[93–98]

The urine color change to vin rosé indicates ferrioxamine in the urine.[92,96] The lack of a color change is not a reliable indication of adequate deferoxamine therapy because not all patients experience vin rosé urine.[92,96] There is also no correlation between the amount of iron ingested, serum iron concentration, and the urine color change.[92]

Deferoxamine can interfere with some laboratory methods used to measure serum iron concentrations and cause falsely low values.[92,93,103,106] Atomic absorptive spectroscopy is a recommended method for monitoring serum iron concentrations once deferoxamine

treatment has been started.[105] When initiating deferoxamine therapy, the clinical laboratory should be contacted to clarify whether deferoxamine will interfere with their serum iron analysis.

Patient Outcome

K.M. was admitted to the pediatric ICU overnight and treated with a constant infusion of deferoxamine at 15 mg/kg/hour for 13 hours. Her GI symptoms resolved, she became more alert, and her vital signs were stable. Her serum iron level was 70 µg/dL the next morning, and she was discharged home that afternoon.

ASSESSMENT OF CENTRAL NERVOUS SYSTEM DEPRESSANT VERSUS ANTIDEPRESSANT INGESTION

Validation of Ingestion

CASE 5-4

Question 1: A.G., a 40-year-old male, was found unconscious in a pool of vomitus with a suicide note. The note stated that he had ingested 30 of his pills. A.G.'s 75-year-old mother called paramedics. When the paramedics arrived, A.G.'s heart rate was 150 beats/minute, BP was 115/70 mm Hg, and respirations were 14 breaths/minute and shallow. A.G. responded only to painful stimuli. The paramedics immediately started an IV line after completing their assessment of his ABCs.

Why should the drug overdose information from this suicidal patient be validated?

Assessing the accuracy of the ingestion history information in adult drug exposures is difficult, and many health care professionals question the validity of information, especially from suicidal patients.[22–25,27] The ingestion history could be inaccurate because

the patient's altered mental status might prevent accurate recollection of what occurred. He may also try to intentionally mislead health care providers to avoid appropriate care. Studies have demonstrated a poor correlation between reported drug ingestions and urine drug test results.[23–25,27,32,33,107] There are also numerous false-positive results that can be misleading because of drug interference.[108,109]

Urine drug screens generally detect all recent drug and substance use, rather than just an overdosed drug. Urine drug screen results, therefore, are not reliable indicators of acute exposures. Every effort should be made to validate the history with information from other sources. In suicidal patients, one should consider all drugs that may have been available to the patient, as well as the patient's presenting symptoms, laboratory tests, and information obtained from family members, police, paramedics, and other individuals who know the patient.[22–25,27]

Interventions by Protocol

Case 5-4, Question 2: In addition to managing the ABCs, what pharmacologic interventions should be authorized for the paramedics to administer to A.G. in addition to the initiation of an IV solution?

GLUCOSE AND THIAMINE

Emergency medical service personnel often have protocols directing them to treat patients who are unconscious from an unknown cause. These protocols generally include administration of glucose, thiamine, and naloxone.[23,27,60,110] If paramedics cannot measure a blood glucose concentration immediately, A.G. should be given 50 mL of 50% dextrose to treat possible hypoglycemia. The risks of hyperglycemia from this dose of glucose are negligible relative to the significant benefits if the patient is hypoglycemic. Thiamine should be administered concurrently with glucose because glucose can precipitate Wernicke–Korsakoff complex in thiamine-deficient patients[111] (see Chapter 90, Substance Use Disorders). Wernicke

encephalopathy is a reversible neurologic disturbance consisting of generalized confusion, ataxia, and ophthalmoplegia. Korsakoff psychosis is believed to be irreversible and is associated with a more prolonged deficiency of thiamine.[111,112] The unconscious patient should also be evaluated for blood loss, sepsis, hypoxia, and evidence of head trauma.[25]

NALOXONE

The pure opioid antagonist, naloxone, is indicated for the treatment of respiratory depression induced by opioids,[110,113] but many emergency medical service protocols authorize paramedics to routinely administer naloxone to all patients with any decreased mental status.[114] Naloxone reportedly has reversed coma and acute respiratory depression in intoxicated patients who have no evidence of opioid use.[60,112] The response of these patients to naloxone might have been secondary to opioids that were not detected by the urine toxicology screens (eg, oxycodone, methadone, fentanyl). Reports of naloxone success in patients without opioid use could also have been the result of responses to other stimuli rather than a response to naloxone.

Administering naloxone to a patient with opioid use disorder can precipitate withdrawal symptoms (eg, agitation, combativeness, vomiting, diarrhea, lacrimation, rhinorrhea) that can further complicate the intoxication picture.[60] Small doses of naloxone should be administered initially to determine the patient's response to this medication. Violent and aggressive behavior can result when sudden increased consciousness is induced by naloxone.[27] This can complicate emergency care in an emergency transport vehicle and put caregivers and patients at risk for trauma.[60]

Initial Treatment

Case 5-4, Question 3: The paramedics arrive at the ED with A.G. 30 minutes after his mother called. A.G.'s heart rate in the ED is 155 beats/minute, BP is 89/50 mm Hg, and respirations have decreased from 14 to 9 breaths/minute,

with assisted ventilation. A.G. remains unresponsive. The paramedics were unable to find any prescriptions or other medications in the house. The mother thinks her son was taking medication for depression. The medical team will try to obtain more details from A.G.'s pharmacy. What initial treatment should be provided for A.G. in the ED?

A.G. should be intubated and mechanically ventilated with 100% oxygen because of his shallow, slow respirations and the likelihood that vomitus could have been aspirated into his lungs. A bolus of IV fluid should be administered to A.G. to determine whether an increase in intravascular fluid volume will increase his BP and improve his mental status.[22,40]

Antidotes

Case 5-4, Question 4: A.G. fills his prescriptions at several pharmacies, and it is taking a while to obtain his medication list. What antidotes can be administered in the ED for diagnostic purposes? Should flumazenil (Romazicon®) be administered?

Theoretically, antidotes such as naloxone, flumazenil, deferoxamine, and digoxin-specific antibody (FAB) fragments could be administered in a hospitalized setting to identify an unknown toxin.[22,26,27,113,115,116] However, the cost and time required for administration, and increased risks from these antidotes, preclude their use for diagnostic purposes without some plausible suspicion of a specific drug ingestion.[113,115]

Organ System Evaluations

Case 5-4, Question 5: How can the initial physical assessment, using an organ systems approach, help in identifying the drugs ingested by A.G.?

The patient's ABCs and CNS and cardiopulmonary functions should be assessed, with special attention to clinical manifestations

that suggest ingestion of a specific class of drugs.[27,40] A.G.'s history of depression suggests that antidepressants, antipsychotics, lithium, or benzodiazepines are candidates for ingestion. An organ system evaluation will help determine whether these (or other) drugs might have been ingested. Commonly used nonprescription medications such as aspirin, acetaminophen, decongestants, and antihistamines, should also be considered because adult drug ingestions usually involve more than one drug.

CENTRAL NERVOUS SYSTEM FUNCTION

Changes in CNS function are probably the single most common finding associated with drug intoxication.[27] CNS depression or stimulation, seizures, delirium, hallucinations, coma, or any combination of these can be seen in intoxicated patients. CNS changes can be the direct result of an ingested drug or may be attributed to other underlying CNS processes or medical conditions.[116] Clinical manifestations of drug overdoses may differ depending on where the patient is in the time course of the intoxication, and the amount of drug(s) ingested.[27,64]

Drugs with anticholinergic properties can produce disorientation, confusion, delirium, and visual hallucinations early in the course of the intoxication; coma can become apparent as toxicity progresses. Generally, overdoses with anticholinergic drugs do not produce true hallucinations, but rather pseudohallucinations. When a patient with an intact baseline mental status presents with psychosis, paranoia, or visual hallucinations, CNS stimulants such as cocaine or amphetamines should be considered.[30,65]

Drug intoxication–induced alterations in CNS function are initially difficult to distinguish from those caused by underlying psychiatric disorders, trauma, hypoxia, or metabolic disorders, such as hepatic encephalopathy or hypoglycemia. However, as time passes, decreased CNS function secondary to drug toxicity is more likely to wax and wane in severity in contrast to the persistent CNS depression that occurs with significant trauma or metabolic disorders. Drug toxicity also rarely produces focal neurologic

findings. Changes in pupil size, reflexes, and vital signs can provide insights into the pharmacologic class of drug involved in the intoxication.[23,27,28]

CNS depression, seizures, disorientation, and other CNS changes that are commonly associated with psychiatric drugs should be evaluated carefully in A.G. For example, A.G.'s pupil size would most likely be dilated if he had ingested a TCA because of the anticholinergic effects of these drugs. TCA intoxications can also cause myoclonic spasms,[27] which are often difficult to differentiate from seizure activity caused by TCA overdoses, although the spasms are often asymmetric and more persistent.[117]

CARDIOVASCULAR FUNCTION

Assessment of heart rate, rhythm, conduction, and measurements of hemodynamic function can also be used to help identify the type of drug ingested. Overdoses of sympathomimetic drugs usually increase heart rate, whereas overdoses of cardiac glycosides or β-blockers can slow the heart rate. Although drugs can increase or decrease heart rate directly, indirect cardiac effects (eg, reflex tachycardia in response to hypotension) also need to be considered. Abnormal heart rates produced by drug overdoses are usually not treated unless accompanied by hypotension or severe dysrhythmias.[27,40]

PULMONARY FUNCTION

Evaluating the rate and depth of respiration and the effectiveness of gas exchange in an intoxicated patient can also help identify drugs ingested. A decrease in respiratory rate is commonly associated with the ingestion of CNS depressants. An increased respiratory rate and depth is generally associated with CNS stimulant toxicity and can also be secondary to respiratory compensation for drug-induced metabolic acidosis.[27] Aspiration of gastric contents after vomiting is common in drug ingestions. Aspiration pneumonitis is the most common pulmonary abnormality associated with significant intoxications.[43] Noncardiogenic acute pulmonary edema has been

associated with salicylate overdoses[80] (especially with chronic intoxications) and drugs of abuse (eg, cocaine and heroin).[114,118–124]

TEMPERATURE REGULATION

Body temperature is an important and sometimes overlooked parameter when assessing potential intoxications.[27,40] Decreased mental status is often associated with a loss of thermoregulation, resulting in a body temperature that falls or increases toward the ambient temperature. Increased body temperature (hyperthermia) caused by overdoses of CNS stimulants (eg, cocaine, amphetamines, ecstasy), salicylates, hallucinogens (eg, phencyclidine), serotonergic agents, or anticholinergic drugs or plants (eg, jimsonweed) can have serious consequences.[27,29,40] Body temperature should be measured rectally to obtain an accurate representation of core body temperature.[125]

Hyperthermia caused by drug overdoses is commonly seen in hot, humid environments or when the intoxication is associated with physical exertion, increased muscle tone, or seizures. In these patients, it is important to obtain renal function tests (eg, BUN, serum creatinine) and a serum creatine kinase measurement to determine whether rhabdomyolysis has occurred secondary to breakdown of muscle tissue.[27,40,125]

GASTROINTESTINAL FUNCTION

The GI tract should be assessed for decreased motility because drug absorption can be delayed or prolonged.[27,126,127] When this is the case, decontamination may be beneficial after an oral ingestion even if a long time has elapsed since the ingestion. The presence of blood in either emesis or stool may suggest ingestion of a GI irritant or caustic substance.[128]

SKIN AND EXTREMITIES

The physical examination should include a thorough examination of the body surface for causes of trauma that may also explain the patient's condition. Examination of the skin and extremities can

provide evidence of drug intoxication, especially with IV or subcutaneous drug injection needle marks.[27] Drugs can be hidden in the rectum or vagina.[27] Drug patches (eg, fentanyl) may be found in hidden areas of the body such as the back of the neck or scrotum. Fluid-filled bullae at gravity-dependent sites that have been in contact with hard surfaces for a long time suggest prolonged coma.[27] Muscle tone should also be assessed.[30] Increased tone or myoclonic spasms can be caused by some drug overdoses (eg, TCAs) and can produce rhabdomyolysis or hyperthermia.[27,125] Dry, hot, red skin may also be an indication of anticholinergic toxicity.[27,40]

In summary, an organ system assessment of A.G. can provide useful insights into the identity of drugs that might have been ingested, the viability of organ function that might have been adversely affected, and the treatment needed.

Laboratory Tests

Case 5-4, Question 6: What laboratory tests should be ordered for A.G.?

The laboratory assessment of an intoxicated patient should be guided by the history of the events surrounding the ingestion, clinical presentation, and past medical history.[22,129] The status of oxygenation, acid–base balance, and blood glucose concentration must be determined, especially in patients with altered mental status such as A.G.[40] Oxygenation can be assessed initially by pulse oximetry, and acid–base status by ABGs and serum electrolyte concentrations.[129,130] A.G. was given oxygen and a bolus of IV fluid on arrival at the ED, and paramedics administered glucose during transportation.

A medical history of organ dysfunction or medical disorders (eg, diabetes, hypertension) that can damage organs of elimination (eg, kidney, liver) will also guide the need for laboratory tests. A serum creatinine concentration and liver function tests (eg, aspartate aminotransferase [AST], alanine aminotransferase [ALT]) should be

ordered. Other more specific tests reflective of his past medical history can be ordered subsequent to a dialogue with his psychiatrist. A complete blood cell count, complete chemistry panel, serum osmolality, and other baseline laboratory tests should be obtained.[27] Pregnancy tests should be considered in female patients of childbearing age because unwanted pregnancies are common causes of overdose.[131,132]

A baseline electrocardiogram (ECG) should be obtained when exposure to a cardiotoxic drug is suspected or whenever the cardiovascular or hemodynamic status is altered.[23,26,40,130] A 12-lead ECG should be ordered because A.G. is likely to have ingested a psychotropic agent. Continuous cardiac monitoring should be instituted because of the significant cardiotoxicity associated with overdoses of these agents. Patients with severe TCA overdoses frequently present with symptoms of coma, tachycardia with a widened QRS interval, seizures, hypotension, and respiratory depression.[133–136]

A chest radiograph is useful when the potential exists for either direct pulmonary toxicity or aspiration.[23,26] A chest radiograph is indicated because A.G. had vomitus in his mouth, and TCAs are associated with the development of acute respiratory distress syndrome and pulmonary edema.[133,137,138]

Qualitative Screening

Case 5-4, Question 7: Should A.G.'s urine and blood be screened to assist in identifying the ingested substance? What is your rationale?

Toxicology laboratory testing can be used to identify the substances involved in a toxic exposure, to exclude substances, or to measure the concentration of substances in serum or other biologic fluids.[24,129,130] The identification and quantification of compounds should be considered as two distinct types of toxicologic testing.[24,139] *Qualitative* screening is used to identify which substance

or class of substances is involved in the toxic exposure. *Quantitative* testing determines how much of a known substance is present.[24]

Screening of various biologic fluids can identify unknown substances. Urine is screened much more commonly than is blood, whereas gastric fluid is rarely evaluated. A urine drug screen is preferred to a blood drug screen because urine generally contains a higher concentration of a drug and its metabolites than do other body fluids.[140]

When reviewing the results of urine screening panels for drugs and other substances, one must remember that the presence of a substance in urine is not necessarily related to a concurrent toxicity. A positive result on a urine screening panel merely indicates that the patient has ingested or has been exposed to the substance, but it does not differentiate between toxic and nontoxic doses. If a drug and its metabolites are eliminated slowly into the urine for a prolonged time, and if the testing methodology detects small concentrations of the substance, urine drug screening could identify the presence of a substance days, weeks, or even months after the exposure (eg, marijuana).[24,130]

It is important to know which drugs or substances are tested at a given laboratory. Many laboratories restrict the number of drugs for which they test because 15 drugs account for >90% of all drug overdoses.[32] Some urine toxicology screens only detect common drugs of abuse (eg, amphetamines, barbiturates, benzodiazepines, cocaine, marijuana, opioids).[130] Some drugs of abuse are not detected on routine drug screening (eg, γ-hydroxybutyrate, ketamine, flunitrazepam).[24] Some analyses detect only antibodies to drug metabolites. For example, a benzodiazepine screen detects oxazepam, a common benzodiazepine metabolite. However, alprazolam and lorazepam are not metabolized to oxazepam and will not be detected in a urine screen. Likewise, an opioid screen may not detect synthetic opioids such as fentanyl and methadone.[130]

Results of qualitative toxicology screening tests are difficult to interpret. False negatives, false positives, cross-reactivity with related drugs, chronicity of exposure, and length of time since last exposure all complicate results.[108,109,130] Urine toxicology screen

results rarely change clinical management of the patient. Monitoring mental, cardiovascular, and respiratory status and other laboratory parameters provide better clues than do the results of a urine toxicology screen.[23,24,129,130,139]

Toxicology screening can be appropriate when the history of a suspected toxic exposure is unavailable, inaccurate, or inconsistent with the clinical findings.[24] However, it is important to know which drugs are detected on a given toxicology screen.[130] A comprehensive qualitative urine drug screen can be considered for A.G. because information about the substance(s) he ingested is not yet known.

Quantitative Testing

Case 5-4, Question 8: Should a quantitative toxicology laboratory test be ordered for A.G. as well? What is your rationale?

After a qualitative urine analysis for drugs, a quantitative analysis of drug concentration in blood can help determine the severity of toxicity and the need for aggressive interventions (eg, hemodialysis).[24,33,130,139] Quantitative tests are especially useful when assessing the potential toxicity of drugs with delayed clinical toxicity or when the toxicity primarily is caused by metabolites (eg, ethylene glycol, methanol). The concentration of a drug in serum is sometimes much more predictive of end-organ damage than are clinical findings (eg, acetaminophen effect on the liver).

Quantifying the amount of drug in serum is useful when (a) the concentration of the substance correlates with toxic effects, (b) the turnaround time for results is rapid, and (c) treatment can be guided by the serum concentration.[32,132,142] To aid in the care of poisoned patients, stat quantitative serum concentrations of acetaminophen, carbamazepine, carboxyhemoglobin, digoxin, ethanol, ethylene glycol, iron, lithium, methanol, methemoglobin, phenobarbital, salicylates, and theophylline should be available at laboratories of large health care facilities.[23,24,33,129,139]

When blood samples are collected to quantitate potentially intoxicating substances, as much information as possible should be obtained about the time course of events to determine whether absorption and distribution of the substance is complete. Serial samples may be needed to determine whether significant absorption is still occurring.[29,30] In contrast to the interpretation of therapeutic serum concentrations of chronically administered drugs, the serum concentration of a substance ingested in an overdose is not likely to be at a steady state.

Quantitative toxicologic testing will likely not benefit A.G. at this point in time because the identity of the ingested substance is unknown. Nevertheless, a serum ethanol concentration could be obtained because alcohol is often ingested concurrently in overdose situations.[132] Most poison centers also recommend obtaining a quantitative acetaminophen level on all intentional ingestions because serious hepatotoxicity can occur if acetaminophen ingestion is missed.[24,129,130]

Assessment

Case 5-4, Question 9: A.G.'s clinical status has not changed in the past 10 minutes. A urine toxicology screen, blood acetaminophen, blood alcohol, and ABGs have been ordered. The 12-lead ECG shows a prolonged QRS interval of 0.13 seconds (normal, <0.1 seconds). No antidotes have been administered. A.G.'s physical examination did not detect any evidence of trauma to his head. His pupils were dilated and slowly responsive to light, and his bowel sounds were hypoactive. What conclusions can be made at this time with regard to the likely substance ingested by A.G.?

Although the ingested substance still has not been specifically identified, the available data provide some clues as to the likely pharmacologic class of drug that was ingested. The presence of CNS depression (A.G. is unresponsive), slowed ventricular conduction (widened QRS on ECG), tachycardia (heart rate, 155 beats/minute), hypotension (BP, 89/50 mm Hg), and decreased GI motility (hypoactive bowel sounds), and the history of a possible

depressive illness (history from mother) are all consistent with a TCA drug overdose. The antidepressant could have been ingested alone or with other agents.

Antidepressant Toxicities

Case 5-4, Question 10: How would the different toxicities of the many available antidepressants affect the treatment of A.G.?

The major pharmacologic effects and toxicities of the antidepressants are similar for all drugs within the same class. When a specific drug within a therapeutic class has not yet been identified, the overdose should be managed as if the ingested drug can produce the most severe toxicity of any drug in the class. Therefore, A.G.'s presumed antidepressant drug overdose should be evaluated and managed initially as TCA (eg, amitriptyline) ingestion.[135,141] Antidepressants with different structures and actions (eg, trazodone [Desyrel®], fluoxetine [Prozac®], sertraline [Zoloft®]) generally do not produce toxicity as severe as that of the TCAs.[135,141,142]

Gastrointestinal Decontamination

Case 5-4, Question 11: If a TCA ingestion is presumed, why might GI decontamination be appropriate at this time?

The longer GI decontamination is delayed relative to the time of ingestion, the less effective it is likely to be because drug absorption will already have occurred. Because the time of ingestion is unknown and A.G. is unresponsive, he probably already has absorbed significant amounts of the drug, making him more vulnerable to aspiration. In addition, A.G. might already have aspirated because he was found in a pool of vomitus. TCA overdoses can also cause seizures, which would be a relative contraindication to GI

decontamination. In consideration of these concerns, many would not support GI decontamination for A.G.[41–44,51–54]

Others might support GI decontamination because TCAs have strong central and peripheral anticholinergic properties that slow GI emptying, which could result in erratic absorption and delayed toxicity, but A.G. would first need to be intubated to protect his airway. Furthermore, TCAs have a large volume of distribution (10–50 L/kg), and both the parent drug and its metabolite undergo enterohepatic recirculation. The half-life of TCAs in overdose situations is 37 to 60 hours. For those reasons, activated charcoal could be reasonably administered in an effort to adsorb any drug that may not yet be absorbed from the GI tract.[49]

Repeated doses of activated charcoal have been used to increase the elimination of TCAs because of the long half-life of TCAs and the enterohepatic recirculation. In clinical studies, multiple-dose activated charcoal has increased the elimination of amitriptyline, but the data are insufficient to support or exclude its use.[47]

MONITORING EFFICACY

Case 5-4, Question 12: How should the effectiveness of GI decontamination be monitored in A.G.?

If activated charcoal is administered, A.G. must first be intubated to protect his airway, and the charcoal must be administered via an NG tube because he is unconscious. The insertion of the NG tube could stimulate the gag reflex, causing vomiting and possible aspiration. A.G.'s lung sounds should be monitored closely to determine whether aspiration pneumonitis is developing, particularly because A.G. was found unconscious and had already vomited.

Activated charcoal, especially in multiple doses, can produce ileus, GI obstruction, or intestinal perforation, particularly when administered to patients who have ingested drugs that slow GI motility.[47,49,101] Bowel sounds must be monitored frequently to ensure that an ileus is not developing. Once the patient passes a charcoal-

laden stool, the activated charcoal can be considered to have successfully passed through the GI tract.

Sodium Bicarbonate and Hyperventilation

Case 5-4, Question 13: According to A.G.'s psychiatrist, he prescribed amitriptyline 100 mg at bedtime for his severe depression. How does this new information alter A.G.'s treatment plan?

This information confirms the assumptions that a TCA was ingested. It also specifically identifies the drug ingested. In TCA ingestions, severe toxicity has been associated with doses of 15 to 25 mg/kg.[98] A.G. ingested a total of 3000 mg based on his suicide note that said he took 30 tablets. If he weighs about 154.32 pounds (70 kg) and was truthful about the amount taken, he ingested a significantly toxic dose (about 43 mg/kg).

On the ECG, TCA toxicity will manifest as tachycardia with prolongation of the PR, QTc, and QRS intervals, ST- and T-wave changes, and abnormalities of the terminal 40-millisecond vector.[98,117,133,136,142–146] TCAs have anticholinergic, adrenergic, and quinidine-like membrane effects on the heart.[117,133,135,141,144] It is believed that the anticholinergic effect causes the tachycardia and the quinidine-like effect causes the ECG changes.

In addition, TCAs are sodium channel blockers.[147] Sodium channel blockade slows the maximum uptake stroke of phase 0 of the action potential and decreases automaticity. Blockade decreases conduction velocity in the Purkinje fibers, which increases the QRS interval.[144] Myocardial depression, ventricular tachycardia, and ventricular fibrillation are the most common causes of death from TCAs.[136] Therefore, admission to the ICU with continuous cardiac monitoring is essential for A.G.[143]

The primary therapy for reversing ventricular arrhythmias and conduction delays is alkalinization of the serum and sodium loading with IV hypertonic sodium bicarbonate.[117,133,135,136,144,145,148] Indications for sodium bicarbonate include hypotension, widened QRS interval

(>100 milliseconds), right bundle branch block, and wide complex tachycardia.[135,145] Alkalinization increases serum protein binding of the TCAs and reduces the amount of free active drug (likely a minor consideration).[116,133,136,145] Correction of the serum pH is beneficial because underlying acidosis worsens TCA-induced cardiotoxicity.[145] Furthermore, sodium bicarbonate has been found useful even in patients with a normal pH because sodium bicarbonate purportedly overcomes the sodium channel blockade and reduces cardiotoxicity.[145,147]

On the basis of A.G.'s tachycardia and a widened QRS segment on ECG, he should be treated with IV sodium bicarbonate with the goal of achieving an arterial pH of 7.45 to 7.55.[136,145] Sodium bicarbonate could have been administered earlier because the suspicion of an antidepressant overdose was strong initially, his ECG demonstrated QRS widening and worsening myocardial conduction, and his BP continued to decline from the time he was first seen by the paramedics. If not monitored closely, the use of IV sodium bicarbonate could introduce the risk of sodium overload and subsequent pulmonary edema.[98,146]

An alternative is to hyperventilate the patient to a pH of 7.5 by adjusting his ventilator setting, thereby reducing the cardiotoxicity of the TCA.[133,136,146] The combination of IV bicarbonate and mechanical ventilation is more likely to produce severe alkalemia. Careful and frequent monitoring of the serum pH of patients on dual therapy is essential.[133,147]

MONITORING EFFICACY

Case 5-4, Question 14: How should the sodium bicarbonate therapy in A.G. be monitored?

Patients intoxicated with TCAs often present with severe acidosis. Large doses of sodium bicarbonate may be required to normalize the arterial pH. The efficacy of sodium bicarbonate administration can be

evaluated by monitoring acid–base status using ABGs, especially if the patient is also being ventilated mechanically.[133,147,148]

Sodium bicarbonate should be administered IV as a bolus of 1 to 2 mEq/kg for a 1- to 2-minute period. Continuous ECG monitoring is needed to monitor results of the bolus on cardiac abnormalities. Repeat bolus doses are administered as needed until the QRS interval narrows and tachycardia slows. Blood pH should be tested after several boluses to determine whether a target pH of 7.5 to 7.55 has been obtained.[145] At a minimum, ABGs should be determined within an hour of starting sodium bicarbonate therapy to determine pH response.[148] Bicarbonate boluses can be followed by a constant sodium bicarbonate infusion of 150 mEq/L to maintain an alkaline pH.[145] ABGs must be monitored frequently to ensure a response.[133,147,148] Serial ECGs to measure the QRS interval are useful for evaluating the efficacy of sodium bicarbonate therapy. A widened QRS interval will generally normalize after the systemic pH has been increased to about 7.5.[148]

Seizures

Case 5-4, Question 15: A.G. gradually developed more severely altered mental status and became comatose, not responding even to painful stimuli. He suddenly experienced a tonic-clonic seizure, which lasted about 1 minute and terminated spontaneously. Should anticonvulsant therapy be initiated for A.G. at this time?

CNS toxicity is common in TCA overdoses. Symptoms include agitation, hallucinations, coma, myoclonus, and seizures.[117,133–136] Seizures can cause significant increases in acidosis and increase cardiotoxicity. Seizures are often seen immediately before cardiopulmonary arrest. Because of the severe consequences of prolonged seizures, aggressive drug treatment with rapid onset of action is indicated, and benzodiazepines are the drugs of choice.[133,136]

Drug overdose–induced grand mal seizures are most commonly single seizures that terminate before drug therapy can be administered.[135] Seizure activity is not expected to persist, so instituting long-term anticonvulsant therapy is not indicated. However, if A.G.'s seizure did not stop within 1 to 2 minutes, a benzodiazepine would have been indicated.[117,133,136] The onset of action of phenobarbital is too slow for acute seizures, and phenytoin is usually ineffective in treating drug toxicity–related seizures.[117] After a seizure, the patient may become more acidotic and hypotensive.[136] Blood gases, creatine kinase, and ECG changes should be monitored immediately after a seizure.

Interpretation of Urine Screens

Case 5-4, Question 16: A.G.'s BP fell to 80/42 mm Hg, and dopamine was started. His pH on repeat ABGs was 7.20. A.G.'s ECG normalized after the administration of 150 mL of sodium bicarbonate by IV bolus. After dopamine, his BP increased to 100/56 mm Hg, and seizure activity ceased. The urine drug screen results were positive for amitriptyline and nortriptyline. Acetaminophen, salicylates, and ethanol were not detected in his blood. Does the presence of nortriptyline indicate that A.G. has ingested other drugs in addition to his amitriptyline?

Nortriptyline is a metabolite of amitriptyline and, therefore, was identified on the urine drug screen. Metabolites, as well as the parent compound, are often identified on comprehensive urine drug screens.[132]

Duration of Hospitalization

Case 5-4, Question 17: How long should A.G. be monitored?

A.G. should be admitted to the ICU and monitored until all evidence of CNS and cardiovascular toxicity has been reversed.[117] There is some controversy over how long symptomatic patients

should be observed. Some believe symptomatic patients need cardiac monitoring for 24 hours after ingestion.[135] Others believe that patients with TCA overdose need to be monitored until they are symptom-free for 24 hours because of a few reports of late development of symptoms.[139] However, 98% of signs of cardiotoxicity and arrhythmias are seen within the first 24 hours of TCA ingestion.[117,134] Because the incidence of late-occurring symptoms is rare, most patients are discharged after they are fully awake.[133] After the toxicity has completely resolved, A.G. should be evaluated by a psychiatrist to determine whether he should be admitted for inpatient treatment of his suicidal ideation.[133–135]

Patient Outcome

A.G. had no further seizure activity. He remained on a dopamine infusion for 8 hours and required several more boluses of IV sodium bicarbonate. The next afternoon, he started to awaken and expressed regret that his suicide attempt was not successful. Arrangements were made to transfer him to an inpatient psychiatric hospital once he was medically cleared.

ASSESSMENT OF ACETAMINOPHEN INGESTION

Mechanism of Hepatotoxicity

CASE 5-5

QUESTION 1: B.W., an 18-year-old female who is about 30 weeks pregnant, presents to the ED 8 hours after ingesting 40 acetaminophen 500-mg tablets. She is depressed and hoped to end her pregnancy by ingesting acetaminophen. Her pregnancy was unplanned, and she has received no prenatal care. B.W. has vomited spontaneously six times since the ingestion and is reporting abdominal pain; her heart rate is 95 beats/minute, BP is 110/74

mm Hg, and temperature is 98.5 °F (36.94 °C). B.W. does not have any chronic diseases, and the remainder of her medical history is unremarkable.

How does an overdose of acetaminophen cause toxicity?

Acetaminophen is metabolized in the liver by glucuronidation and sulfation. The mixed-function oxidase system cytochrome P-450 (CYP) 2E1 metabolizes a portion of the acetaminophen to the highly reactive metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI). In therapeutic doses, this metabolite is detoxified in the liver by glutathione. At toxic serum acetaminophen concentrations, the glucuronidation and sulfation metabolic pathways become saturated. Usually, NAPQI is detoxified by conjugation with glutathione, but increased amounts of the toxic metabolite deplete hepatic glutathione stores. When glutathione stores are decreased to about 30% of normal, the toxic metabolite binds to liver cells, resulting in the characteristic centrilobular hepatic necrosis seen in acetaminophen overdoses.[149–152]

Complication of Pregnancy

Case 5-5, Question 2: How does B.W.'s pregnancy change the management of her acetaminophen ingestion?

Pregnancy does not alter the initial approach to the assessment or treatment of potentially toxic ingestions, and assessment should focus initially on the pregnant patient.[153,154] Overdoses during pregnancy are often associated with attempted abortions, depression, prior loss of a child or children, potential loss of a lover, or economic reasons.[131,132,153,154] Intentional ingestions of analgesics, prenatal vitamins, iron, psychotropic agents, and antibiotics account for 74% of the overdoses during pregnancy.

The fetus is at risk when the pregnant patient overdoses on acetaminophen because acetaminophen crosses the placenta. The fetal liver can oxidize acetaminophen to its hepatotoxic metabolite by 14 weeks of gestation.[151] However, the fetal liver has only about 10%

of the capability of the adult liver to metabolize acetaminophen. The fetal liver can conjugate acetaminophen with both glutathione and sulfate, but detoxification by glutathione conjugation appears to be decreased.[155,156]

In studies of maternal acetaminophen toxicity, most of the pregnant females survived without damage to themselves or their babies. However, there were also maternal and fetal deaths as a result of overdose.[155,157] Acetaminophen overdoses during pregnancy did not appear to increase the risk of birth defects or adverse pregnancy outcomes unless the mother suffered severe toxicity, emphasizing the need to treat the mother promptly.[149,155]

Gastrointestinal Decontamination

Case 5-5, Question 3: Should GI decontamination be initiated for B.W.? What is your rationale?

B.W.'s acetaminophen ingestion occurred 8 hours ago; therefore, the drug is likely to be totally absorbed, and no GI decontamination should be initiated.

Estimating Potential Toxicity

Case 5-5, Question 4: How should the potential toxicity of the acetaminophen ingestion be assessed in B.W.?

Acetaminophen toxicity results from ingestions >150 mg/kg or >7.5 g total in adults. However, serum acetaminophen concentrations better predict acetaminophen-induced hepatotoxicity than does the dose of acetaminophen acutely ingested.[158,159] The Rumack–Matthew nomogram is used in the United States to assess the potential for hepatotoxicity from acute overdoses of acetaminophen.[160,161] The treatment line is defined by a serum acetaminophen concentration of 200 µg/mL at 4 hours after

acetaminophen ingestion and 30 µg/mL at 15 hours after ingestion on a semilogarithmic graph.[152] Many prefer to be more conservative and use the bottom line of 150 µg/mL at 4 hours to begin treatment as histories of ingestion are often inaccurate. The serum acetaminophen concentration is plotted on a graph against the time of ingestion.[159] The nomogram predicts the probability that the AST or ALT will be >1000 IU/L and can be used to guide therapy by indicating whether a specific acetaminophen concentration is in the toxic range.[162] The nomogram is useful only for acute ingestions because it underestimates the potential for toxicity in chronic acetaminophen ingestions. It should be noted that although the nomogram is used to plot acetaminophen concentrations for all patients, it has been validated only in healthy nonalcoholic adults.[152]

Acetaminophen Treatment Nomogram

Case 5-5, Question 5: When is the preferred time to measure a serum acetaminophen concentration?

Acetaminophen absorption generally is complete within 1.5 to 2.5 hours of ingestion of solid or liquid dosage forms.[159] The Rumack–Matthew nomogram is not applicable before 4 hours after ingestion because it is based on complete drug absorption.[159] Most clinical laboratories can complete their assays and report acetaminophen serum concentration results within 2 hours.

Stages of Acetaminophen Toxicity

Case 5-5, Question 6: What are the clinical signs and symptoms of acetaminophen toxicity?

Early detection of an acetaminophen overdose is difficult because there are no characteristic early diagnostic findings. Toxicity appears in stages that may overlap and are not clear-cut. About 30 minutes

to 24 hours after ingestion, the patient may exhibit anorexia, nausea, vomiting, malaise, and diaphoresis that can easily be attributed to other causes. The second stage of acetaminophen toxicity occurs about 24 to 48 hours after ingestion and is the stage in which hepatotoxicity develops. Hepatotoxicity is universal by 36 hours after ingestion. An AST measurement is the most sensitive measure of hepatotoxicity because AST abnormalities always precede evidence of actual liver impairment.[152,160,163]

In the third stage, 72 to 96 hours after ingestion, maximal liver dysfunction is evident with the return of anorexia, nausea, vomiting, and malaise. Symptoms can range from mild to fulminant liver failure with hepatic encephalopathy, coma, and hemorrhage. AST and ALT serum concentrations can be >10,000 IU/L. There are also increases in bilirubin and INR measurements, as well as abnormalities in glucose and pH readings. Death, if it occurs, is usually a result of multiorgan failure or hemorrhage caused by hepatic failure. Most deaths occur 3 to 5 days after exposure. Patients who survive this stage go into recovery.[152,160,163]

Antidotes

Case 5-5, Question 7: What antidote for acetaminophen ingestion should be considered in B.W.? How does the antidote work, and when is it most effective?

Toxicity is determined by the results of a serum acetaminophen concentration measured at least 4 hours after ingestion.[159] NAC is the antidote for acetaminophen toxicity. It is a sulfhydryl donor that converts to cysteine, which is subsequently converted to glutathione.[149,160,162,163] NAC acts as a glutathione substitute and directly combines with the toxic acetaminophen metabolite, NAPQI, reducing it to a nontoxic cysteine conjugate.[163] NAC can also substitute for sulfation, which increases the nontoxic metabolism through that route as well. NAC increases intrahepatic microcirculation and is believed to possess hepatoprotective

properties, showing some value even after liver damage has already occurred.[149,160]

Instituting therapy early with NAC is essential. When NAC is started within 8 to 10 hours of the ingestion, hepatotoxicity resulted in only 1.6% of cases. In patients who were started on NAC >10 hours after ingestion, 53% developed liver damage.[152,160]

Safety of *N*-Acetylcysteine in Pregnancy

Case 5-5, Question 8: Is NAC safe to use during pregnancy?

Acetaminophen overdose in pregnant patients should be managed in the same manner as in nonpregnant patients.[155–157] If the life of the pregnant patient is not saved, the fetus will not survive (unless the child is near term and is emergently delivered). NAC therapy is not contraindicated in pregnant patients and might be helpful because it crosses the placenta and can protect the fetus from hepatotoxicity.[155,157]

NAC therapy appears to be protective for both the pregnant patient and fetus.[152,155,158–160,162,163] When used as an antidote for acetaminophen overdose in pregnancy, NAC did not appear to cause toxic effects to the fetus.[149,152,155,157] The probability of fetal death was increased with the delay in NAC treatment after acetaminophen overdose.[152,156,160]

Route of Administration of *N*-Acetylcysteine

Case 5-5, Question 9: The 9-hour acetaminophen concentration in B.W. was 170 µg/mL. By what route should NAC be administered?

This concentration of acetaminophen at 6 hours is above the treatment line on the Rumack–Matthew nomogram.[161] Because there was some delay from the time of ingestion to presentation at the ED

and B.W. was already vomiting, it will be more difficult for B.W. to tolerate oral NAC. For this reason, IV NAC is recommended.

An FDA-approved sterile, pyrogen-free formulation of NAC is available as Acetadote®.[164–166] The use of IV NAC is not completely risk-free because of a possible anaphylactoid reaction during the first dose of the IV NAC. The incidence of adverse reactions ranges from 14.3% to 23%. Patients with asthma and patients with ectopy should receive the drug slowly and carefully, while being watched for symptoms of a reaction.[166]

A majority of the adverse reactions include nausea, vomiting, urticaria, flushing, and pruritus. Bronchospasm, angioedema, hypotension, and death have rarely occurred and must be carefully monitored when the IV route is being used.[167,168] Most reactions occur during or just after the first 15 minutes of the initial antidote infusion and appear to be dose related.[168] Because of the timing issue, the first dose of IV NAC is usually administered for 60 minutes instead of 15 minutes, even though a study comparing adverse reactions in the two infusion rates did not show clinically significant differences.[166,169]

Intravenous *N*-Acetylcysteine

Case 5-5, Question 10: How should IV NAC be administered to B.W.?

The FDA-approved IV NAC protocol is the same 20-hour dosing regimen used in Europe, known as the Prescott protocol.[164,165,166] A 150 mg/kg loading dose of NAC in 5% dextrose is infused IV slowly for 60 minutes while watching for symptoms of a possible anaphylactoid reaction. This is followed by a maintenance dose of 50 mg/kg infused for 4 hours and then followed with a 100 mg/kg dose infused for 16 hours. This regimen provides a total of 300 mg/kg NAC during the 20 hours after the loading dose.[166]

Oral *N*-Acetylcysteine

Case 5-5, Question 11: Once she is able to tolerate oral NAC treatment, what dosing regimen would be appropriate for B.W.?

The standard oral NAC protocol is based on the original clinical studies.[163] The loading dose of NAC is 140 mg/kg orally using either the 10% or 20% mucolytic solutions that were formulated for inhalation therapy. Seventeen additional maintenance doses of 70 mg/kg of NAC are administered at 4-hour intervals after the initial dose, for a total of 72 hours of therapy. This provides a total of 1330 mg/kg NAC during 72 hours.[170] Because oral NAC contains a sulfhydryl group, the substance has a very disagreeable taste and smell (similar to that of rotten eggs) that commonly results in nausea and vomiting in the patient. To mask the unpleasant taste and odor, NAC is diluted to a concentration of 5% using a carbonated beverage or fruit juice.[163] Because the entire dose of oral NAC passes through the liver, high concentrations are produced, which is seen as an advantage of oral therapy.[164]

Shorter oral NAC regimens are currently being used based on the efficacy of IV therapy.[171,172] Short-course oral NAC follows the same 20-hour time course as IV NAC. Patients receive the usual 140 mg/kg oral loading dose of NAC, followed by 70 mg/kg every 4 hours for five additional doses (20 hours of therapy). Serum acetaminophen, liver function tests, and INR are repeated at 20 hours after the loading dose, which is after the fifth maintenance dose. If 20-hour liver function tests and coagulation studies are normal and the acetaminophen level is less than the lower limits of detection, NAC can be stopped. A repeat set of liver function tests is recommended at 36 hours after ingestion. In other versions of the 20-hour NAC therapy, the dosage regimen is the same, but the laboratory studies are measured initially, and then at 16, 36, and 48 hours after ingestion.[172]

Efficacy of *N*-Acetylcysteine

Case 5-5, Question 12: Which route of NAC administration is more effective?

There is no proven evidence that one route of NAC administration is superior to the other.[161,164,173–175] Patient outcome after an acetaminophen overdose depends more on the time after the ingestion that treatment begins rather than on the route of administration of NAC. Patients who are started on NAC within 8 to 10 hours of ingestion, regardless of the route, rarely develop hepatotoxicity. Patients who present late or have a delay in the time of NAC treatment have higher rates of hepatotoxicity.[150,161,164,170,174–176]

In one comparative study of IV NAC to oral NAC therapy, both were effective in reducing hepatotoxicity when therapy was initiated within 10 hours of ingestion. Vomiting delayed oral administration of the drug, but IV administration resulted in significantly longer delays in instituting therapy.[174] IV NAC avoids the problems of the vomiting patient, but oral NAC is safer. Oral NAC is associated with nausea and vomiting, whereas IV NAC is associated with bronchospasm, urticaria, and angioedema during administration.[149,160] In addition, oral therapy is much less expensive.[176]

Although the time of initiation of therapy is one of the key factors in reducing hepatotoxicity from acetaminophen ingestions, length of therapy has become another factor.[175,177] Because the duration of therapy with the IV formulation is 21 hours, patients with severe toxicity may be undertreated. It is essential that the patient be reevaluated at the end of the 21 hours to make sure that acetaminophen levels are not detectable and that liver enzymes are trending downward significantly. If there is still measurable acetaminophen and liver enzymes are still elevated, therapy with NAC must be continued.

Starting oral NAC may take less time to prepare than does IV NAC therapy and is less expensive. If the patient presents early after an acetaminophen ingestion and does not have nausea and vomiting, oral therapy would be indicated. If the patient presents late (>10 hours after ingestion) with signs and symptoms of hepatotoxicity

along with intractable nausea and vomiting, IV NAC should be instituted at once.[164,170]

Monitoring Efficacy of *N*-Acetylcysteine

Case 5-5, Question 13: How should the efficacy of NAC therapy be monitored in B.W.?

The effectiveness of NAC intervention in B.W. should be monitored by daily assessment of her acetaminophen concentration (as long as it is still measurable), AST, ALT, total bilirubin, glucose, and INR. The AST and ALT serum concentrations typically increase within 36 hours (range, 24–72 hours) of ingestion.[160,174] As the hepatic damage continues, the liver enzymes may peak at several tens of thousands units, even with NAC therapy. In most patients, AST and ALT begin to decline after 3 days and then return to baseline values.[160]

In a small number of patients, usually those who presented late after the ingestion, fulminant hepatic failure may develop. Symptoms of severe or persistent acidosis, coagulopathy, a significantly increased serum creatinine, and grade III to IV encephalopathy are consistent with fatal outcomes in patients with fulminant hepatic failure. Liver transplantation might be a consideration for these patients.[152,178–181]

Duration of *N*-Acetylcysteine Therapy

Case 5-5, Question 14: How long should NAC administration be continued?

The original NAC dosing protocol was based on an assumption that the half-life of acetaminophen was 4 hours. After five half-lives (20 hours), the acetaminophen should be metabolized, and NAC could be discontinued. An NAC dose of 6 mg/kg/hour was determined to be necessary based on the rate of glutathione

turnover relative to NAPQI production. To ensure that patients received an adequate NAC dose, the FDA recommended that this dose be changed to 18 mg/kg/hour for 72 hours.[182] This recommendation serves as the basis for the traditional 72-hour oral course of NAC therapy.

When using the traditional 72-hour oral course of NAC, therapy can be discontinued if the liver function tests are trending toward normal, other laboratory tests (ie, coagulation studies, glucose, pH, bilirubin) are within normal ranges, and acetaminophen is no longer present in the serum. As long as acetaminophen is present, it can be metabolized to NAPQI and cause further toxicity.[162,171,182] Continued NAC will not be harmful to the patient and can be beneficial.

When using the shorter 20-hour course of oral NAC, if liver function tests and coagulation studies are normal and the 20-hour acetaminophen concentration can no longer be measured in the serum, NAC therapy can be stopped.[172] However, if 20-hour liver function test or coagulation study results are abnormal, or if the 20-hour acetaminophen concentration measurement reveals acetaminophen still present in the serum, NAC therapy should be continued for at least another 24 hours.[173,174] Laboratory tests should be repeated every 24 hours, and the patient's progress must be monitored closely. If the patient is not improving, NAC should be continued until the patient recovers, receives a liver transplant, or dies.[152]

At this time, there is no consensus as to the best route of NAC administration, optimal dosage regimen, or optimal length of therapy.[160,164,182] There is consensus, however, that for optimal results, NAC therapy must be instituted within 10 hours of ingestion.[149,160,164,170,173,176] For patients who do not exhibit any signs of hepatotoxicity, shorter course NAC therapy reduces the amount of NAC administered to the patient, decreases the quantity of laboratory tests, shortens hospital stay, and is less costly.[164,171,182]

N-Acetylcysteine Toxicity

Case 5-5, Question 15: How should the toxicity of NAC therapy be monitored in B.W.?

With the exception of vomiting, oral NAC is remarkably safe and has not been associated with toxicity.[149,161,164] Oral NAC must be retained for a minimum of 1 hour after ingestion to be successfully absorbed. If B.W. vomits within an hour of her oral NAC dose, the dose should be repeated. If she experiences protracted vomiting, administration of antiemetic drugs (eg, ondansetron, metoclopramide) or placement of a duodenal feeding tube can improve GI tolerance.[164,183,184] If the patient cannot tolerate oral liquids, NAC therapy should continue via IV administration.

IV NAC therapy has been associated with anaphylactoid reactions in up to 14% of the patients. Although most reactions are not severe, bronchospasm, angioedema, and respiratory arrest have been reported.[149,160,164,182] Patients should be monitored for allergic and anaphylactoid reactions when NAC is administered via IV infusion. Most reactions can be avoided by infusing the NAC loading dose slowly for 60 minutes.[149,160,164]

Patient Outcome

B.W. continued to have nausea and vomiting and had difficulty tolerating liquids. IV NAC was continued. An obstetrics consultation was requested to evaluate B.W.'s pregnancy. Fetal monitoring was instituted during her hospital admission. A sonogram was taken of the fetus. Once B.W. saw the child's image from the sonogram, her depressed mood seemed to lift. Approximately 36 hours after ingestion, her acetaminophen level was no longer detectable, and her liver function tests showed a mild elevation of her AST at 274 units/L and an ALT of 188 units/L. Her INR and total bilirubin values were normal at 0.7 seconds and 0.8 mg/dL, respectively.

B.W. was seen by a psychiatrist. She was scheduled for counseling and prenatal classes. B.W. seemed eager to attend the classes, and she talked enthusiastically about the pregnancy when

family members came to visit. Because of B.W.'s pregnancy, the decision was made to continue NAC for a full 72-hour course, with the goal of protecting the fetal liver as much as possible. Six weeks later, she had a normal delivery of a healthy 6.06-pound (2.75 kg) newborn female.

CONCLUSION

Unfortunately, there is no set formula to treat all poisoned patients. Each exposure is unique and patient-specific factors must be considered. Treatment of the poisoned patient often involves controversy because solid, evidence-based science to support a given decision is frequently lacking. When challenged with a poisoning exposure, consult with a poison control center by calling 1-800-222-1222, where consultation is available 24 hours a day in the United States.

End-of-Life Care

Victoria F. Ferraresi and Mary Mihalyo

CORE PRINCIPLES		CHAPTER CASES
1	End-of-life care consists of palliative and hospice care. It is ideally introduced early in the disease progression to provide support to patients of all ages with a serious chronic or life-threatening illness. Medicare patients who enter a hospice program agree to relinquish their regular Medicare benefits because they relate to the terminal illness and accept the palliative rather than the curative approach that will be provided by hospice. Hospice provides all care related to the hospice diagnosis under a managed-care model at a fixed reimbursement.	**Case 6-1 (Question 1)**
2	In 2008, the Hospice Conditions of Participation were updated to include a	**Case 6-1 (Question 2)**

	review of the medication profile as part of the initial assessment of new patients. The medication regimens of hospice patients should be continually reviewed and updated, with unnecessary, ineffective, or duplicative medications discontinued.	
3	Patients near end of life can experience a number of distressing symptoms. These should be anticipated and treated in a timely manner that is acceptable to the patients and their families.	**Case 6-1 (Question 3), Table 6-3**
4	Well-trained pharmacists can improve medication management for hospice patients, while helping the hospice manage their drug costs.	**Case 6-1 (Question 2)**
5	Many barriers exist regarding pain management and the use of opioids.	**Case 6-1 (Question 4)**
6	Effective pain management uses a variety of approaches.	**Case 6-2 (Question 1)**
7	Pain and symptom management may at times require an aggressive approach.	**Case 6-3 (Questions 1–3)**

INTRODUCTION

Hospice and Palliative Care

End-of-life care is care provided in the period leading up to an inevitable death and can be provided under hospice or palliative care or outside of a formal program.[1] *Hospice care* and *palliative care* are

similar, but distinct terms sharing the common belief that the relief of suffering is a long-standing, central, and fully legitimate aim of medicine. The basic principle of end-of-life care is to optimize the quality of life for the patient and family in the last weeks and months of life as well as to provide support for the family beyond the end of life into bereavement.

Palliative care, which includes hospice care, is ideally introduced early in the disease progression to provide support to patients of all ages with a serious chronic or life-threatening illness. It can be provided concurrently with other treatments to cure or reduce disease or it can be provided independently. The word *palliation*, derived from the Latin word *pallium* (a cloak), has been defined as "treatment to reduce the violence of a disease."[2,3] The World Health Organization and the National Consensus Project for Quality Palliative Care define palliative care as a patient- and family-centered approach that improves the quality of life of patients and their families who are facing a life-threatening illness, by preventing and relieving suffering through early identification, assessment, and management of pain and other physical, psychosocial, and spiritual problems while affirming life and regarding death as a normal process.[4,5] Palliative care can be provided wherever patients receive care: in the hospital, physician practice sites, ambulatory clinics, community pharmacies, and long-term care facilities.

Hospice and palliative medicine became a recognized subspecialty of internal medicine in 2006, awarded by the American Board of Medical Specialties and is currently a subspecialty certification for nine other specialty areas, including anesthesiology, emergency medicine, and pediatrics.[6] The Joint Commission offers an Advanced Certification Program for Palliative Care to recognize hospitals that provide high-quality palliative care services.[7] There is currently no specialty certification available for pharmacists in hospice or palliative care, although there are 26 American Society of Health-System Pharmacists (ASHP)-accredited PGY2 (post-graduate year 2) residencies in palliative care and pain management.[8,9] A small number of advanced degree programs are

available, offering additional training for pharmacists in palliative care, and ASHP offers a certificate program in pain management.

Hospice, originally a place or way station for people making a pilgrimage, is considered both a philosophy of care and a place to deliver care. *Hospice care* focuses on the palliation of pain and other symptoms when active treatment to cure a terminal illness ends. Hospice care can be delivered in a building designated as a hospice, in the patient's home, or in a facility where the patient resides. As a programmatic model for delivering palliative care, hospice care provides an interdisciplinary team approach to individualized symptom management (eg, pain), as well as psychosocial, emotional, spiritual, and bereavement support for the patient and his or her family and caregivers during the last months of life while no longer pursuing active or curative treatment.[10]

Hospice Care in the United States

Most hospice care in the United States is provided under the Medicare Hospice Benefit by hospice programs certified by the Centers for Medicare and Medicaid Services (CMS). According to estimates of the National Hospice and Palliative Care Organization (NHPCO), there were approximately 4639 Medicare-certified hospice programs in the United States in 2018.[10] Of all deaths of Medicare recipients in the United States, 50.7% occurred under hospice care, with 1.55 million beneficiaries enrolled in a hospice program for 1 day or more during 2018. During the Medicare demonstration project (1980–1982, just before the creation of the Medicare Hospice Benefit as part of the Social Security Act), 93% of home hospice patients had cancers of various types.[11] In 2018, hospices provided care for patients with a wider variety of terminal illnesses (eg, cancer [29.6% of all admissions], circulatory or heart disease [17.4%], dementia [15.6%], respiratory disease [11%], stroke [9.5%], chronic kidney disease [2.2%], and other [14.7%]).[10] This care was provided primarily in the patient's home (55.6%), in an inpatient facility (0.8%), or in another unspecified location (6.6%).[10]

Adults age younger than 65 years account for <5.1% of the hospice population under the Medicare benefit.[10] Pediatric patients, who may range in age from prenatal to young adults, represent a unique challenge for hospice care. Regulatory, financial, cultural, and educational barriers play a role in diminished access to hospice care for pediatric patients because treatment is often pursued late in the progression of disease.[12–14] Referrals for pediatric oncology patients to palliative care often occurs late in the course of illness.[15] Although states are required to offer hospice care to pediatric patients under Medicaid and other state programs as part of the Affordable Care Act expanding benefits to improve coordination of care,[16] community-based pediatric palliative care may be a better initial alternative for these patients and can serve as a bridge to subsequent hospice admission.[14]

Medicare Hospice Benefit

The regulatory framework for the provision of hospice care under Medicare is defined in 42 CFR (Code of Federal Regulations) Part 418, Medicare and Medicaid Programs: Hospice Conditions of Participation and is funded from Part A (the hospital portion) of Medicare.[17,18] Patients are eligible for this benefit if, in the opinion of two physicians (ie, patient's primary care physician and hospice medical director), the natural course of their disease will result in death within 6 months. The hospice medical director determines and documents the terminal diagnosis and any other conditions contributing to the terminal prognosis. Eligibility for hospice can continue beyond the initial certification if the hospice medical director recertifies eligibility at defined intervals, called certification periods. Other insurance payers generally follow this criterion. In electing this benefit when signing the hospice election form, patients accept the palliative rather than the curative approach provided by hospice. All care related to these diagnoses is coordinated, provided, and paid for by the Medicare-certified hospice program. CMS has clarified that virtually all diagnoses are related to the terminal diagnosis and

prognosis; if a program disagrees, the hospice medical director must specifically document why a diagnosis is not related.[19,20]

Hospice care is provided (and reimbursed) under Medicare at four levels, all of which can be modified at any time based on a patient's condition or caregiving needs:

1. Routine home care (day-to-day care in the home, skilled nursing or assisted living facility)
2. Continuous home care (when more skilled care in the home is required owing to symptom management or a caregiving crisis) where a nurse or home health aide provides care for at least 8 hours in a day (ending at midnight); 50% of this care must be provided by a nurse.
3. General inpatient care (reimbursement for an inpatient stay in a hospital or skilled nursing facility related to symptoms that cannot be managed in the home)
4. Inpatient respite care (up to 5 days in a skilled nursing facility) to give the caregiver a break or respite

Most care, consisting of pain and symptom management and assistance with activities of daily living, as well as psychosocial support, is provided to hospice patients at the routine level of care.

Unlike home health care under Medicare, patients in hospices do not have to be homebound. They may freely visit their primary care provider (ie, physician or nurse practitioner) for any reason, including reasons that are documented as unrelated to their terminal illness. The primary care provider will be paid directly by Medicare. Patients may use their regular Medicare benefits for the documented unrelated illnesses; visits to providers for care or treatments unrelated to the primary hospice diagnosis are not limited or restricted. Patients may revoke (terminate) their election of the Medicare Hospice Benefit at any time (eg, end hospice care to pursue curative treatment or seek treatment outside the hospice plan of care [POC] or if they move outside of the hospice service area). Patients may, at a later date, choose to return to hospice care or

change to a different hospice program, without restrictions or loss of benefits.[18]

It is common for patients to be referred to hospice when death is imminent. Median lengths of stay have declined, from 37.1 days during the Medicare demonstration project (1980–1982) to 26 days in 2005 and to 18 days in 2018.[10,11] Approximately 27.9% of patients admitted to a hospice program in 2018 died or were discharged within 7 days; 40% received services for ≤14 days.[10]

Hospice programs have historically received a fixed daily payment to provide all care related to the terminal diagnosis (eg, medications, supplies, durable medical equipment, procedures, home health aides, provider visits, spiritual care, bereavement services). The reimbursement rates for the four levels of hospice care under the Medicare Hospice Benefit are established each summer for the following fiscal year, effective October 1. A baseline reimbursement rate is set, along with an adjustment for wage differentials (the wage index) based on the local cost of living. There are additional adjustments made for rural hospices and for the submission of quality data. Effective in fiscal year 2014, hospices that do not submit quality data receive a 2% reduction in reimbursement for all levels of care.[21]

Programs generally have high costs at the start of care due to personnel costs involved in the admission, assessment, and development of the initial POC, as well as obtaining medications, medical equipment, and medical supplies. High costs are also encountered nearer to the end of a patient's life, when new problems can appear and symptoms often intensify. In recognition of this, CMS implemented a tiered hospice payment system in January 2016. This system consists of higher payments at the start of care (for days 1–60) and for the 5 days before death near the end of life via a service intensity add-on (SIA) to account for greater care needs during these periods.[22]

Hospice reimbursement rates have not kept pace with rising costs. The total unadjusted hospice daily payment rate for routine level of care increased from $146.63 to $161.89 per day from 2011 to the first quarter of 2016 (just before when rates moved to the two-tier

model), an increase of 2.1% annually.[22,23] For fiscal year 2021, the rate for days 1 to 60 has been increased to $199.25 per day for hospices that submit quality data from $194.50 in 2020, a 2.44% increase.[24,25] In 2018, drug prices for the 267 top products used by older adults in the United States increased on average by 5.8%. In the period from 2010 to 2018, these drug price increases peaked at a 15.8% rise with a 1.6% general inflation rate in 2014.[26] In addition, prices have increased for generic drugs because of fewer generic drug manufacturers (less competition), drug shortages, and the U.S. Food and Drug Administration (FDA) Unapproved Drug Initiative, which converted some generic drugs back to branded products.[27–31] Prices for drugs for pain and inflammation increased by 15.7% in 2014. This resulted in some generic drugs traditionally used extensively for palliation (eg, atropine, chlorpromazine, promethazine, prochlorperazine) no longer being used as first-choice agents by many hospice programs.

In reviewing hospice beneficiary use of Medicare Part D, CMS has reminded Medicare Part D Plans, pharmacies, and hospices that hospices are required to pay for virtually all care (including all related medications) for patients in hospices (via Part A). An initiative to block Part D access to such patients was subsequently reversed by CMS with the clear expectation that hospices provide analgesics, antiemetics, laxatives, and anxiolytics and to coordinate drug coverage with the Part D plans.[32–34] Hospices are allowed to establish formularies, but if the hospice does not provide a related medication for any reason, the beneficiary may not use their Part D plan to obtain it. The result has been hospices paying for many more medications than they did in the past (ie, covering medications used to treat rather than just palliate related conditions). Effective October 1, 2020, an addendum must be submitted as part of the hospice election at admission and subsequently if requested by the patient (or their representative) that specifically identifies noncovered items, services, and drugs.[25] This must be submitted at the start of care (within 5 days) and thereafter within 72 hours of the request.

These variables (ie, referrals to hospice later in the course of terminal illness, higher costs at the start of care, shortened lengths of

stay, higher drug costs, providing more medications) have placed intense pressure on hospice programs to manage expenses. Because it is difficult to influence the time when patients are referred to hospice, the duration of time in hospice care, or the inherently higher costs when patients are first enrolled into hospice, the management of drug costs has taken a high priority in providing cost-effective hospice care.

Improving Patient Care and Managing Drug Costs

In 2008, the Hospice Conditions of Participation were updated to be more patient centered and outcome oriented.[18] Coverage of medications is mandated as described in 42 CFR §418.106 Drugs and biologicals, medical supplies, and durable medical equipment: ". . .drugs and biologicals related to the palliation and management of the terminal illness and related conditions, as identified in the hospice POC, must be provided by the hospice while the patient is under hospice care." CMS has stated that it will be the rare exception that a hospice patient is taking a medication that is not paid for by the hospice.

The regulations state that the comprehensive assessment must "take into consideration" the drug profile (42 CFR §418.54). This is defined as "[a] review of all of the patient's prescription and over-the-counter drugs, herbal remedies and other alternative treatments that could affect drug therapy" and is to include the following:

- Effectiveness of drug therapy
- Drug side effects
- Actual or potential drug interactions
- Duplicate drug therapy
- Drug therapy currently associated with laboratory monitoring

Although the regulations specify that the hospice registered nurse complete the initial and comprehensive assessments, pharmacists are uniquely qualified, as part of the hospice interdisciplinary team, to perform or provide input on the medication assessment.

Well-trained pharmacists can improve patient care and positively affect the fiscal margins of hospice programs by discouraging inappropriate use of medications, establishing evidence-based formularies, promulgating prior authorization policies for specific targeted drugs, establishing policies for adhering to the use of generic drugs, and managing the quantities of medications to be dispensed. In addition to managing drug expenditures, pharmacists provide drug information both to patients and providers and work integrally with other members of the hospice health care team to improve the safe and effective use of medications and collaborate in providing pain and symptom management.[35–52] In 2016, ASHP published a comprehensive guideline detailing the role and contribution of the palliative and hospice care pharmacist (PHP).[53]

Referral to Hospice

ELIGIBILITY

CASE 6-1

Question 1: M.P. is an 89-year-old female referred to hospice for end-stage Alzheimer dementia. She lives in a residential care home for the elderly with a hired caregiver. Her husband has been unable to care for her at home for some time because she requires full assistance with all activities of daily living. She was recently hospitalized with aspiration pneumonia and a urinary tract infection (UTI) and completed a course of intravenous (IV) vancomycin and piperacillin/tazobactam. Her medical history includes osteoporosis, coronary artery disease (CAD), chronic obstructive pulmonary disease (COPD), hypercholesterolemia, and hypothyroidism. She is not oriented to person, place, or date. Her speech is unintelligible or nonsensical. She cannot feed herself, but will eat the thick pureed food that is fed to her. She is bedbound and incontinent of urine and stool. She is restless and irritable at times, especially at night. Her Palliative Performance Scale Version 2 (PPS) is 30%. Weight is 112 pounds (50.80 kg), decreased from 135 pounds (61.23 kg) a year ago, and a recent serum albumin is 2.2 g/dL.

What criteria does M.P. meet for eligibility for hospice services under the Medicare Hospice Benefit?

Patients with chronic diseases (eg, Alzheimer disease, Parkinson disease, stroke, heart failure, lung disease) can be sufficiently ill and debilitated to need custodial care, but might not be sufficiently ill to meet the definition of a terminal illness. This differentiation between terminally ill versus chronically ill requiring custodial care is important because to qualify for hospice services under the Medicare Hospice Benefit, patients must be at a stage where death is expected within the next 6 months. For cancer diagnoses, the presence of widespread metastatic disease may make this prognosis more easily evident. However, for other chronic diseases, this is not as clear. Further, a cancer diagnosis will have a different disease trajectory than do chronic debilitating diseases. There are three primary models for decline in the face of serious illness that must be considered in determining hospice eligibility as well as in creating a treatment plan. In cancer, patients typically show steady disease progression followed by a sudden steep decline leading to death. Patients with respiratory and cardiac disease may show a long decline with acute exacerbations and deterioration followed by sudden death. Chronic debilitating diseases such as Parkinson disease, amyotrophic lateral sclerosis (ALS), and dementia generally show a prolonged gradual decline, with death often attributed to an intervening comorbidity such as pneumonia, sepsis, or malnutrition.[54]

The Medicare Administrative Contractors (MACs) have issued criteria to assist in the determination of eligibility for hospice care, as well as criteria to meet a 6-month terminal prognosis for a number of diseases. These criteria, or local coverage determinations (LCDs), provide guidelines for meeting an overall decline in clinical status, for meeting non–disease-specific data to establish a baseline, for establishing the effect of comorbidities (eg, renal failure, liver disease), and for the submission of documentation for having met criteria. Criteria have been established for patients with cancer and noncancer diagnoses, and these criteria are used in the determination of eligibility for service and reimbursement.[55] Criteria for the noncancer diagnoses have been developed for ALS, dementia as a result of Alzheimer disease and related disorders, heart disease, human immunodeficiency virus disease, liver disease,

pulmonary disease, renal disease, stroke, and coma. Patients with cancer are eligible if they present with metastatic disease or progression from an earlier stage to metastatic disease with either a continued decline in spite of therapy or if they decline further disease-directed therapy.

The determination of whether M.P. meets eligibility requirements for Medicare Hospice Benefits must be based on the established LCDs for dementia as a result of Alzheimer disease. These criteria include the following, from the Functional Assessment Staging Tool (FAST) Scale[56–58]:

- Stage 7 or beyond, according to the FAST Scale
- Stage 7A: Can speak six or fewer intelligible words in a day or during an interview
- Stage 7B: Speech ability limited to the use of a single intelligible word in a day or during an interview
- Stage 7C: Cannot ambulate without assistance
- Stage 7D: Cannot sit up without assistance
- Stage 7E: Loss of ability to smile
- Stage 7F: Loss of ability to hold head up independently
- Unable to ambulate without assistance
- Unable to dress without assistance
- Unable to bathe without assistance
- Urinary and fecal incontinence, intermittent or constant
- No consistently meaningful verbal communication; stereotypical phrases only or the ability to speak is limited to six or fewer intelligible words
- One of the following within the past 12 months: aspiration pneumonia, pyelonephritis, septicemia, decubitus ulcers (multiple, stages 3 and 4), fever (recurrent after antibiotic treatment)
- Inability to maintain sufficient fluid and caloric intake with 10% weight loss during the previous 6 months or serum albumin <2.5 g/dL

The Palliative Performance Score Version 2 (PPS) (**Table 6-1**) gradates the extent of disability and can be used to assist in the determination of hospice eligibility.[59] M.P. meets the previous criteria and is eligible for hospice because of her Alzheimer disease. She clearly is debilitated. She is unable to speak intelligently, cannot feed herself, is not oriented to time or place, is incontinent of urine and stool, has lost about 20% of her weight during the past year, has a serum albumin of 2.2 g/dL, and has a PPS rating of 30% (ie, totally bedbound, unable to do any activity, confused). In addition, she has a number of comorbidities, experienced a recent episode of aspiration pneumonia, and finished a course of antibiotic therapy.

Table 6-1
Palliative Performance Score (PPS) Version 2

PPS Level (%)	Ambulation	Activity and Evidence of Disease	Self-care	Intake	Conscious Level
100	Full	Normal activity and work No evidence of disease	Full	Normal	Full
90	Full	Normal activity and work Some evidence of disease	Full	Normal	Full
80	Full	Normal activity with effort Some evidence of disease	Full	Normal or reduced	Full
70	Reduced	Unable to do normal job/work Significant disease	Full	Normal or reduced	Full
60	Reduced	Unable to do hobby/housework Significant disease	Occasional assistance necessary	Normal or reduced	Full or confusion
50	Mainly sit/lie	Unable to do any work Extensive disease	Considerable assistance required	Normal or reduced	Full or confusion
40	Mainly in bed	Unable to do most activity Extensive disease	Mainly assistance	Normal or reduced	Full or drowsy with or without confusion
30	Totally bedbound	Unable to do any activity Extensive disease	Total care	Normal or reduced	Full or drowsy with or without confusion
20	Totally bedbound	Unable to do any activity Extensive disease	Total care	Minimal to sips	Full or drowsy with or without confusion
10	Totally bedbound	Unable to do any activity Extensive disease	Total care	Mouth care only	Drowsy or coma with or without confusion
0	Death				

Instructions: PPS level is determined by reading left to right to find a "best horizontal fit." Begin at left column reading downward until current ambulation is determined; then, read across to next and downward until each column is determined. Thus, "leftward" columns take precedence over "rightward" columns.

MEDICATION MANAGEMENT

Case 6-1, Question 2: M.P. has no known allergies. Her current medications are memantine 10 mg twice daily, aspirin 81 mg once daily, alendronate 70 mg weekly, esomeprazole 20 mg daily, lovastatin 20 mg with dinner, megestrol 40 mg/mL 5 mL (200 mg) twice daily, levothyroxine 0.1 mg daily, multivitamin daily, beclomethasone metered-dose inhaler one puff daily, albuterol 2.5 mg/ipratropium 0.5 mg via nebulizer every 4 hours as needed for wheezing or shortness of breath, acetaminophen 325 to 650 mg every 6 hours as needed for mild pain or fever, olanzapine 5 mg at bedtime as needed for restlessness and aggressive behavior, milk of magnesia 30 mL daily for constipation, and a bisacodyl suppository 10 mg every 3 days as needed if there is no bowel movement. The hospice medical director has determined that the aspiration pneumonia, UTI, and COPD are related to M.P.'s terminal prognosis. What is your assessment of M.P.'s medication regimen? Which medications is the hospice required to provide, and which might be discontinued?

Hospices are required to provide (pay for) all medications related to the terminal diagnosis and secondary diagnoses that contribute to the terminal prognosis within the hospice POC. The POC is the individualized plan of treatment developed for each patient formulated at the start of care and updated regularly by the interdisciplinary group or team (IDG/IDT). The Conditions of Participation mandate that the IDG be composed of a physician, registered nurse, social worker, and a pastoral or other counselor.[18] A registered nurse coordinates the implementation of the POC. Some hospice program IDGs have incorporated a pharmacist into the group to review medication issues.

The large array of medications being taken by M.P. is similar to the medication lists of many hospice patients. These patients are often elderly and have a long history of several chronic medical conditions for which they have been taking multiple medications. In most cases, the medication lists of patients who are admitted into a hospice program have seldom been reviewed, updated, or modified in light of

the present medical situation. Admission to a hospice program represents a change in the level of care and is the most appropriate time for a review and reconciliation of all medications to ascertain the necessity of each, with the goal of optimizing efficacy and minimizing the potential for adverse effects, medication errors, and inappropriate costs.

In reviewing medications for the elderly, *The Beers Criteria for Potentially Inappropriate Medication Use in Older Adults* is frequently used to identify medications that may cause adverse events and subsequent harm. In the 2019 version, under “Intent of Criteria,” it states that the criteria are not intended for use in the hospice and palliative care setting.[60] While alerting clinicians to the potential for problems with included medications, this does acknowledge that in end-of-life care, medications are often used specifically for their adverse effects, such as anticholinergics to reduce sialorrhea (drooling) in patients with ALS, doxepin for sedation or itching, and mirtazapine for sedation or appetite stimulation and should not necessarily be avoided in these patients.

Because M.P. is to be enrolled into a hospice program, her care should not be focused on curative treatments, but rather on the management of discomforting symptoms and on improving her quality of life in the time remaining. M.P.’s medications should be analyzed with the goal of simplification. Unnecessary medications should be discontinued and alternatives added to manage two or more symptoms concurrently. The hospice medical director has determined that CAD, COPD, UTI, aspiration pneumonia, and multiple wounds are related to M.P.’s terminal prognosis and thus are identified as secondary diagnoses for hospice care. The following changes should be considered:

Acetaminophen. This analgesic is often helpful in relieving mild pain, particularly in immobile elderly patients.[61] A trial of around-the-clock acetaminophen could be helpful, and the hospice would pay for it.

Albuterol/ipratropium combination. The hospice program is required to pay for medications related to M.P.’s aspiration

pneumonia and COPD. This combination inhalation formulation (or the components as separate products) should be continued if she is able to participate in her nebulizer treatments and it improves her breathing (see Chapter 19, Chronic Obstructive Pulmonary Disease and Chapter 107, Geriatric Drug Use).

Alendronate. This bisphosphonate drug can be discontinued because the treatment of osteoporosis is not an important consideration at this terminal stage of her life nor is it related to her terminal prognosis. Thus, the hospice would not cover it. Furthermore, M.P. is bedbound; alendronate should be ingested in the upright position, and patients should remain upright after taking the medication to decrease the risk of alendronate-induced esophageal irritation (see Chapter 110, Osteoporosis). Pain that she may experience from osteoporosis can be treated with analgesics.

Aspirin. The low-dose aspirin is intended to decrease the risk of cardiovascular clotting. The aspirin will not increase M.P.'s comfort or quality of life. It would be covered by her Medicare Hospice Benefit, and can be continued unless her primary care provider prefers its discontinuation or she experiences adverse effects.

Beclomethasone. This patient is not functioning well cognitively (ie, not oriented to time, person, or place) and would be unable to effectively time the inhalation of a breath to the actuation of her metered-dose inhaler and it should be discontinued. If needed, a systemic corticosteroid (eg, prednisone) might improve her COPD symptoms and also improve her appetite and sense of well-being. The potential for adverse effects is modest with short-term corticosteroid use.

Bisacodyl, milk of magnesia. Constipation in patients with terminal illnesses is common, occurring in as many as 87% to 90% because of decreased gastrointestinal (GI) motility with advanced age, metabolic disturbances, decreased physical activity, lack of adequate fiber and fluid intake, and use of constipating medications (eg, opioids, anticholinergics, psychotropic agents).[62–65] The milk of magnesia, with an occasional bisacodyl suppository,

has been an adequate laxative regimen for this patient; however, the milk of magnesia should be discontinued if her renal function deteriorates. If an opioid is later prescribed for M.P., a mild stimulant laxative (eg, senna) can be added, from two tablets at bedtime up to eight tablets daily.[66] Osmotic agents such as polyethylene glycol (PEG), oral sorbitol, or lactulose can be prescribed if needed. Mineral oil 30 mL daily is an option if the stool is hard; however, mineral oil should not be considered for M.P. because of her risk of aspiration. Bulk-forming laxatives should also be avoided in this population because they may not ingest adequate water to prevent a fecal impaction. In cases of refractory constipation, the use of methylnaltrexone bromide, an opioid antagonist available as a subcutaneous injection and an oral tablet, can reverse opioid-induced constipation by antagonizing opioid effects within the GI tract without affecting systemic analgesia.[67–70] This quaternary derivative of naltrexone does not cross the blood–brain barrier. Dosing is weight based and should be adjusted if a patient's creatinine clearance (CrCl) is <60 mL/min and the patient is in severe hepatic impairment. The most common adverse events in adults with advanced illness are abdominal pain, flatulence, nausea, dizziness, and diarrhea.[67] Other FDA-approved alternatives for opioid-induced constipation are naloxegol, naldemedine, and lubiprostone (see Chapter 24, Lower Gastrointestinal Disorders).

Esomeprazole. This proton-pump inhibitor may be unnecessary because alendronate-induced esophageal or GI irritation would not be an issue subsequent to its discontinuation. However, if a proton-pump inhibitor is needed, nonprescription generic omeprazole or lansoprazole is preferred because they are more cost-effective.[71] If a patient such as M.P. cannot swallow intact tablets, a capsule formulation can be opened with the contents mixed with soft food and swallowed intact.

Levothyroxine. This thyroid medication should be continued until M.P. is no longer able to swallow. This medication, however, would not be covered under her Medicare Hospice Benefit, which is

based on her Alzheimer disease, and was deemed not related to the terminal prognosis.

Lovastatin. Cholesterol-lowering agents are not necessary during the last 6 months of life and can be discontinued without resulting in harm to M.P.[72] Lovastatin would not improve the quality of her life at this stage of her terminal illness and would not be covered by her Medicare Hospice Benefit.

Megestrol. The progesterone derivative, megestrol, in doses of 400 to 800 mg daily, can substantially stimulate appetite and induce weight gain.[73,74] If an undernourished hospice patient desires to eat more, the patient or their family may desire an appetite stimulant. It is unclear whether stimulation of appetite in a cognitively impaired patient will result in weight gain or improved nutritional status. Because the benefits in this situation are unclear, the potential of adverse effects (eg, venous thrombosis) of megestrol needs to be considered, especially in M.P., who is not ambulatory and had been taking low-dose aspirin for prevention of cardiovascular clotting.[75] If M.P. is given an oral corticosteroid, as discussed previously, she may experience improved appetite as an added benefit, thus negating the need to utilize megestrol acetate.

Memantine. Because the *N*-methyl-D-aspartate (NMDA) antagonist, memantine, has been modestly effective in improving performance in patients with moderate-to-severe Alzheimer disease, but with decreasing effectiveness over time, it is probably of limited utility for M.P.[76] (see Chapter 108, Geriatric Neurocognitive Disorders). It would be reasonable to taper and discontinue M.P.'s memantine subsequent to discussion with appropriate hospice team members and M.P.'s family.[77,78] It can be restarted if her behavior deteriorates. If she continues with it, the hospice would provide it.

Multivitamins. Multivitamins and other nutritional supplements are unlikely to improve M.P.'s comfort or quality of life. The discontinuation of these drugs would simplify medication administration, decrease the potential for medication errors, and decrease costs.

Olanzapine. An antipsychotic (eg, olanzapine, haloperidol, quetiapine) is often prescribed off-label to manage the agitation and confusion encountered by patients with dementia. Behavioral modifications can be tried (see Chapter 108, Geriatric Neurocognitive Disorders), but paranoid or delusional behavior may require drug therapy. Small doses of antipsychotics, such as haloperidol or olanzapine, may offer a dual effect and be very useful in treating opioid-induced nausea and vomiting, although randomized clinical trials demonstrating efficacy are lacking.[79,80] They would be covered by M.P.'s Medicare Hospice Benefit. Quetiapine is the agent of choice when more sedation is required and has replaced the use of chlorpromazine because of cost considerations.[71]

SYMPTOM MANAGEMENT

The National Consensus Project for Quality Palliative Care has developed Clinical Practice Guidelines for Quality Palliative Care.[5] The purpose of this document "is to promote access to quality palliative care, foster consistent standards and criteria, and encourage continuity of palliative care across settings." In *Domain 2: Physical Aspects of Care*, guidelines and criteria are provided for interdisciplinary collaboration using available scales and other tools, for the assessment, documentation, and treatment of pain and other symptoms that are acceptable to both the patients and their families as a preferred practice.[5] The Center to Advance Palliative Care (CAPC) provides tools, education, communication, and training for practitioners to provide optimal palliative care.[81]

CASE 6-1, QUESTION 3: As soon as the hospice admission and assessment is completed, the nurse, in consultation with the IDG, develops a plan for symptom management and orders a comfort kit for M.P. What are the components of this kit, and why is it useful?

Some hospices use an order set or a general comfort kit to provide medications to treat anticipated symptoms for a specific patient.[82,83] These medications are placed in the home or facility where the patient resides. This facilitates the availability of medications to patients who encounter anticipated symptoms and is convenient when caregivers are instructed by the patient's primary care provider or the hospice physician to provide the medication to the patient. Patients at end of life experience a large number of symptoms including pain, anorexia, cachexia, weakness and fatigue, dyspnea, cough, nausea and vomiting, dysphagia, constipation, diarrhea, dry mouth, oral sores, wounds and pressure sores, edema, ascites, incontinence, confusion, delirium, anxiety, and depression.[84]

In general, the prevalence of each symptom is difficult to measure or predict and demonstrates a high degree of variability. The occurrence of symptoms, however, can vary significantly, even within the last week of life, and the need for frequent assessment of patients cannot be overemphasized. Some combination of morphine, lorazepam, haloperidol (or olanzapine), ondansetron, and an anticholinergic agent generally provided as a concentrated oral liquid, an orally disintegrating tablet (ODT), or a rectal suppository are commonly ordered for hospice patients. Drugs that can palliate more than one symptom, such as morphine for pain or dyspnea, or haloperidol or olanzapine for agitation or nausea, are particularly suited to inclusion in a comfort kit.

Morphine. Every hospice patient should have a short-acting opioid available for the palliation of unrelieved dyspnea and pain. Although morphine can cause respiratory depression, small doses are very effective in controlling dyspnea by multiple mechanisms: vasodilation, reduced peripheral vascular resistance, inhibition of baroreceptor responses, reduction of brainstem responsiveness to carbon dioxide (the primary mechanism of opioid-induced respiratory depression), and lessened reflex vasoconstriction caused by increased blood P_{CO_2} levels. Opioids can reduce the anxiety associated with dyspnea and might also act directly on opioid receptors present in the airways.[85–90] They can be given in low doses

orally, sublingually, parenterally, or via inhalation for this purpose without causing respiratory depression. A Cochrane Review, however, showed that due to the small number of randomized, blinded, controlled studies, the evidence for the use of opioids to palliate dyspnea was of low quality.[91] In addition, no evidence to support the use of nebulized opioids was found, although this route may be useful if patients are experiencing intolerable side effects from systemic agents.[92] **Table 6-2** provides an overview of both the nonpharmacologic and pharmacologic treatment of dyspnea.

Table 6-2
Treatment of Dyspnea at End of Life

Nonpharmacologic Methods
Pursed-lip breathing Upright position Relaxation Meditation Use of a fan or open window to circulate air over the face
Pharmacologic Therapy
Systemic opioids (short-acting agents) in small doses given orally, sublingually, or via injection can be given every 1–2 hours as needed.
Long-acting agents can be added to supplement the routine use of short-acting opioids.
Inhaled opioids deliver medication via nebulization directly into the airway, avoiding first-pass metabolism, allowing use of smaller doses, theoretically minimizing side effects such as drowsiness. May cause local histamine release, leading to bronchospasm. Use nonpreserved sterile injectable products. More cumbersome and expensive owing to use of nebulizer and nonpreserved parenteral products; evidence does not show that nebulized opioids provide greater benefit than does nebulized saline.
Agents: morphine 2.5–10 mg in 2 mL of 0.9% saline; hydromorphone 0.25–1 mg in 2 mL of 0.9% saline; fentanyl 25 µg in 2 mL of 0.9% saline
Generally given every 2–4 hours as needed for breathlessness
Benzodiazepines are useful for the anxiety associated with breathlessness.

Hospice patients generally do not have IV access (ie, an IV catheter) into which medications can be easily administered. As a result, medications are primarily administered orally and, occasionally, by sublingual, buccal, transdermal, rectal, or subcutaneous (if an infusion is warranted) routes of administration. When patients lose the ability to swallow near the end of life (or have a condition that precludes swallowing), the sublingual or buccal routes of administration are the most useful, especially if drugs are lipophilic. The use of ODTs may also be useful at this time. Morphine is hydrophilic, and although some of it might be absorbed across the mucous membranes, the primary clinical effect probably results from GI absorption after the drug has trickled down the back of the throat.

Oral morphine sulfate, in a concentration of 100 mg/5 mL (20 mg/mL), is commonly dispensed in a 30-mL bottle at the beginning of hospice care. This bottle of morphine can provide 60 doses of 10 mg, and, at this concentration, only 0.5 mL of morphine needs to be administered. Patients should be provided with appropriate oral dosing syringes or use the dropper provided by the manufacturer to prevent dosing errors. Oxycodone or hydromorphone, in comparable adjusted doses, can be substituted for morphine when needed. There is no evidence demonstrating the superiority of any of these over the others in severe cancer pain.[93]

Lorazepam. A short-acting benzodiazepine (eg, lorazepam 0.5 mg every 4 hours as needed) is useful for the treatment of anxiety (see Chapter 83, Anxiety Disorders). Patients, especially those with respiratory symptoms, can experience episodes of extreme anxiety near the end of life, and low doses of a benzodiazepine can provide effective palliation.[94] Caution should be used to not overuse these drugs in the elderly because they can increase the risk of falling or cause paradoxic reactions and worsen delirium or restlessness. The combined use of benzodiazepines with opioids increases the risk of respiratory depression and potentially fatal overdose and should be used with extreme caution in the lowest possible doses.[95,96]

Haloperidol. Small doses of haloperidol (eg, 0.5–1 mg) are useful for the treatment of restlessness, delirium, or nausea and vomiting.[97,98]

Olanzapine. Low-dose olanzapine (2.5–5 mg) can be used to manage restlessness, delirium, or nausea and vomiting, and can be used as an alternative to haloperidol.[97] It is available in multiple dosage forms including an ODT.

Anticholinergic agent. As death approaches, patients can have difficulty in clearing pharyngeal secretions and, as a result, generate a sound commonly known as a death rattle.[99,100] Although patients are often unconscious at this point, this sound can be very distressing to those nearby.[101,102] A long-standing practice is to use an anticholinergic agent (eg, glycopyrrolate, hyoscyamine, scopolamine, atropine) in an attempt to prevent these pharyngeal secretions from forming. Systematic reviews found these agents to be no more effective than placebo.[103,104] Nonetheless, anticholinergic medications continue to be widely prescribed in end-of-life care. Patient positioning and gentle suctioning can remove secretions already present. If used, this treatment modality is usually initiated after the patient has become obtunded; if begun too early, patients might develop problems with thickened bronchial or pulmonary secretions, tachycardia, delirium, dry mouth, urinary retention, or other adverse anticholinergic effects.[105] Glycopyrrolate, available as a tablet, injectable formulation, and oral solution, is a good choice for an anticholinergic agent because it minimally crosses the blood–

brain barrier. The 1-mg tablets could be crushed and placed under the tongue every 8 hours. Hyoscyamine is available as oral tablets, ODT, oral sustained-release tablets, sublingual tablets, oral liquid, oral solution, and injection. The ODT, sublingual tablets, or oral solution of hyoscyamine can be given in a 0.125- to 0.25-mg dose sublingually every 4 hours as needed. Scopolamine transdermal patches have a slow onset of action (blood levels are detected 4 hours after application)[106] and are of limited utility in this situation. The oral or sublingual administration of atropine ophthalmic solution 1% is convenient to administer. Recent shortages and price increases have made it less cost-effective.[71] Families and caregivers must be instructed not to use this in the eye.

Case 6-1, Question 4: The hospice nurse for M.P. has difficulty finding oral morphine sulfate available from a pharmacy and difficulty in finding a pharmacy willing to accept a faxed or an electronic prescription. Why is morphine so difficult to obtain, and how should the nurse manage this problem?

Providing relief for pain or other symptoms with opioids is often difficult owing to numerous barriers. Patients and caregivers are often fearful of opioids, or mistakenly believe these medications will cause addiction or hasten death.[107,108] Pharmacists can create barriers by not having opioids in the pharmacy, sometimes because of the fear of robbery, fear of investigation by drug regulatory agencies, or insufficient appreciation of the usefulness of opioids in pain management and palliative care.[109,110] In response to the opioid crisis, recent legislative and regulatory changes in some states have restricted quantities of controlled substances that can be dispensed and mandated the use of prescription drug monitoring programs (PDMPs). Patients with cancer and those who are terminally ill may be exempt from these requirements.[111–113] Pharmacists who are inexperienced in providing service to hospice patients might not be knowledgeable about federal regulations governing the provision of controlled substances to hospice patients. Federal statutes, as well as most state statutes, permit prescriptions for Schedule II controlled

substances for hospice patients to be faxed. According to the CFR (21 CFR 1306.11) paragraph (g):

A prescription prepared in accordance with 1306.05 written for a Schedule II narcotic substance for a patient enrolled in a hospice care program certified and/or paid for by Medicare under Title XVIII or a hospice program which is licensed by the state may be transmitted by the practitioner or the practitioner's agent to the dispensing pharmacy by facsimile. The practitioner or the practitioner's agent will note on the prescription that the patient is a hospice patient. The facsimile serves as the original written prescription for purposes of this paragraph (g) and it shall be maintained in accordance with 1304.04(h).[114]

Electronic prescribing of controlled substances (EPCS), including Schedule II medications, is now legal per federal DEA regulations in all 50 states.[115,116] Some states mandate the electronic prescribing of all controlled substances. The SUPPORT (*S*ubstance *U*se-Disorder *P*revention That *P*romotes *O*pioid *R*ecovery and *T*reatment) for Patients and Communities Act requires the use of EPCS for all controlled substances under Medicare Part D by January 1, 2021, although it has not been fully implemented.[117]

The process of ordering controlled substances for use by hospice patients at home can take many hours, and sometimes as much as an entire day. Hospice providers should anticipate possible difficulties when placing orders for Schedule II controlled substance medications. M.P.'s nurse should take the time to address any concerns that M.P.'s caregivers and family may have about these medications (ie, how they may affect her, any worries about addiction, side effects) and allow ample time to order them so that symptoms can be managed as they develop.

CASE 6-2

QUESTION 1: G.G., a 40-year-old female, is admitted to hospice with stage IV ovarian cancer, metastatic to her pelvis, liver, and lungs. She was diagnosed after many months of nonspecific gastric distress and bloating. On laparotomy, she was evaluated as stage III and underwent a total abdominal hysterectomy and bilateral salpingo-oophorectomy and tumor debulking at that time. She has

undergone subsequent chemotherapy and repeated tumor debulkings. In the past 6 months, her weight has decreased from 175 pounds (79.37 kg) to 153 pounds (69.38 kg; she is 62 inches [157.48 cm] tall). Her primary problems are constant nausea, constipation, and gripping abdominal pain, which she characterizes as burning and twisting. She quantifies the pain as 8 of 10 (on a 0- to 10-point scale) and describes the pain as one that moves into her groin and leg. Her family is unhappy about the drowsiness she experiences from her medications; they believe she is overmedicated. She is starting to have difficulty swallowing. She has no known allergies. Her current medications include fentanyl transdermal system 75 µg/hour every 72 hours, extended-release morphine sulfate capsules 50 mg three times daily (usually intended for once-daily administration), docusate sodium 250 mg daily, lansoprazole 30 mg daily, and lorazepam 0.5 mg every 4 hours as needed for nausea and anxiety.

What is the most accurate assessment of her pain management regimen?

G.G. is currently using two long-acting opioids (ie, fentanyl transdermal and sustained-release morphine that is being dosed too frequently), but is still unable to achieve relief of her pain, which is probably neuropathic pain (described as burning and twisting). It is estimated that up to 39% of patients with cancer pain have neuropathic pain.[118–120] This may be caused by tumor growth around nerves, postoperative nerve damage, chemotherapy-induced neuropathy, or following radiation therapy. Opioids alone may be of limited value or may require higher than usual dosing.[118] The addition of adjuvant analgesics such as antidepressants, anticonvulsants, and local anesthetics play an important role in treating neuropathic pain[121] (see Chapter 55, Pain and Its Management).

The use of two long-acting agents is duplicative and should be replaced with one opioid. Methadone may be a better long-acting agent for G.G. because it has activity against neuropathic pain (see Chapter 55, Pain and Its Management) and can reduce the amount of medication she uses. Methadone is a µ-opioid receptor agonist, blocks the NMDA receptor and monoaminergic reuptake transporter for serotonin.[122–124] Clinicians find it very effective for intractable neuropathic pain, but studies do not show methadone to be superior to other opioids.[125,126] Advantages of using methadone for G.G. include long half-life, high bioavailability, excellent absorption across mucous membranes, lack of active metabolites, and lower cost. All

dosage forms of methadone, including the oral solution are long-acting ones. Use of the oral solution may be useful when patients lose the ability to swallow as death approaches. Disadvantages in using methadone are its long and variable elimination half-life, drug–drug interactions, prolongation of the QTc interval, and the variability of dosing equivalence with other opioids. Dosing methadone is complex and should be undertaken by experienced clinicians.[124–127]

When converting fentanyl and morphine to methadone, the following should be considered: (a) patient adherence and ability to follow prescription directions, (b) use of an appropriate conversion formula, (c) converting a transdermal formulation of fentanyl to an oral opioid formulation, and (d) a supplemental opioid for breakthrough pain.

Because of its long and variable elimination half-life, the dose of methadone should generally be adjusted only once every 5 to 7 days, and patients must be able and willing to precisely follow directions for its use. The methadone prescribing information can be used for the conversion, with a general rule of thumb being that the initial methadone dose should not exceed 30 mg/day.[128] An alternative, conservative dosing conversion scheme developed by a panel of experts in hospice and palliative care for patients who are opioid tolerant is presented in **Table 6-3**.

Table 6-3

Dosing Conversion to Methadone in Patients Who Are Opioid Tolerant

Oral Morphine or OME/Day	Oral Methadone Dose (No >30 mg Initially)
<60 mg oral morphine or OME	Give 2.5–7.5 mg methadone/day
60–199 mg oral morphine or OME AND patient age <65 years	10:1 conversion 10 mg OME:1 mg oral methadone
≥200 mg oral morphine or OME AND/OR age >65 years	20:1 conversion 20 mg OME:1 mg oral methadone

OME, oral morphine equivalent.

white paper. *J Pain Symptom Manage*. 2019;57(3):635–645.e4. © 2018 American Academy of Hospice and Palliative Medicine. With permission.

Safety guidelines recommend electrocardiographic monitoring before and during methadone use[129,130]; the need for this in terminally ill patients should be balanced by life expectancy and goals of care. Caution should be used in patients with electrolyte abnormalities (hypokalemia or hypomagnesemia), impaired liver function, heart disease, prolonged QT syndrome, or the use of other QTc-prolonging drugs (eg, amiodarone, azithromycin, citalopram, fluconazole, haloperidol, ondansetron).[127,129,130]

Once the conversion is made, the calculated dose is adjusted and the dosing interval is set at every 12, 8, or, rarely, every 6 hours, based on patient age, previous use of opioids, and current clinical status. Clinical judgment is vital in individualizing a regimen for each patient based on his or her needs.

Before calculating the conversion to methadone for G.G., an important consideration in patients using transdermal fentanyl is an assessment of its absorption. Fentanyl from the transdermal system is absorbed through several layers of the skin and deposited in the subcutaneous fat, from which it is absorbed into the systemic circulation.[131] It is generally observed that transdermal fentanyl is not effective in very thin, cachectic patients. In those cases, the conversion would be made without including the fentanyl. The patch would be removed at initiation of the first methadone dose and supplemented with medication for breakthrough pain if needed. In patients using multiple patches, one patch can be removed every 3 days. Despite weight loss, G.G. (62 inches [157.48 cm] and 153 pounds [69.38 kg]) is not cachectic, and the fentanyl should be included when calculating the conversion of her current opioid dose to a comparable methadone dose. In this patient, her sustained-release morphine formulation (50 mg three times daily) is equivalent to 150 mg/day of oral morphine. Her fentanyl transdermal system 75 μg/hour is equivalent to about 150 mg/day of oral morphine.[132] (This is based on a conversion ratio of parenteral to oral morphine of 1:3 in patients who are opioid tolerant, rather than the 1:6 ratio that is used

in the dosing table in the Duragesic® prescribing information.) G.G.'s total oral morphine equivalents (OMEs) per day are 150 plus 150 mg, or 300 mg. Her caregiver reports that she generally takes 150 mg of oral morphine solution daily for breakthrough pain, and yesterday she used 180 mg. This brings the total daily OME to 480 mg, and we would use the 20:1 conversion from **Table 6-3** for conversion of OMEs to methadone. The calculated dose of oral methadone is 24 mg/day. This is a conservative amount; in certain situations, an experienced clinician may choose to start with a higher daily dose. For example, the methadone prescribing information uses a conversion for 480 OMEs of 8% to 12%, which would result in a methadone dose of 48 mg/day.[128]

G.G. can be started on methadone 7.5 mg every 8 hours or 10 mg every 12 hours. Because she is relatively young, has been using opioids for some time, and has severe pain (quantified at 8 of 10), a methadone dose of 7.5 mg every 8 hours (ie, 22.5 mg/day) would be appropriate. The dose can be increased, if needed, based on her clinical response after 5 to 7 days. This smaller initial dose would accommodate for some incomplete cross-tolerance from the morphine and fentanyl and for any fentanyl that remains in her system for the next several days. Patients who have been on much higher doses of opioids, alternatively, can be converted during a period of several days (eg, converting one-third of the previous daily dose of opioid every 3 days). This is an especially useful method for converting opioid doses for thin, cachectic patients who have been on multiple transdermal patches. A clinician should be in touch with G.G. frequently during the first several days after her conversion to methadone. A telephone call should be made 2 to 4 hours after the first dose to assess for efficacy and toxicity (primarily somnolence, confusion, or nausea) and then daily for 5 days. If pain relief with the first dose does not last for the entire dosing interval, it can be adjusted, or G.G. can be instructed to take a one-time extra dose of methadone.

An added benefit in changing to methadone for G.G. is a financial one for the hospice. Outpatient prescription prices for long-acting opioids are very steep and significantly add to hospice costs. The

prudent use of methadone can improve overall pain management and keep costs in check. When methadone is not appropriate, generic extended-release morphine is a good second choice. Transdermal fentanyl should be reserved for patients who cannot take oral medication or for when there are significant compliance issues. Extended-release oxycodone is an option when patients cannot tolerate morphine, have significant renal impairment, or have other contraindications to its use. By converting to methadone, G.G.'s daily cost for the opioid alone will decrease substantially, while still providing appropriate and effective pain management.

G.G. will also need a supplemental analgesic for breakthrough pain. Some practitioners use small doses of methadone, 2.5 or 5 mg, as often as every 3 hours. This is a good choice in a well-supervised (ie, inpatient) setting with nurses familiar with the use of methadone. However, if caregivers treat methadone as if it were morphine, which is much more commonly used for breakthrough pain, the risk of overmedicating the patient is very real. This can have disastrous consequences, especially in frail, elderly patients. Because G.G. is not in an inpatient setting and has tolerated morphine well in the past, 30 mg or 1.5 mL of morphine 100 mg/5 mL (20 mg/mL) can be prescribed to be taken every 2 hours as needed for breakthrough pain.

G.G. should also start a bowel regimen; the use of a stool softener alone is inadequate.[62–65] The nurse should perform a rectal examination to determine if stool is present in the rectal vault. An enema or suppository can be given if needed and then senna or PEG can be taken on a routine basis.

Because the fentanyl transdermal patches and the extended-release morphine have been discontinued, they should be properly discarded. The safe disposal of controlled substances is important in preventing drug diversion. Hospices are required to educate patients and their caregivers at the time of admission about proper drug disposal and must have policies and procedures for the management and disposal of controlled substances.[18] Options for disposal of controlled substances include take-back events, mail-return programs, and DEA-registered collection receptacles.[133] With

the enactment of the SUPPORT for Patients and Communities Act of 2018, hospice personnel are allowed to dispose of controlled substances for their patients by following criteria specified in the law (Section 3222, Disposal of Controlled Substances of a Hospice Patient by Employees of a Qualified Hospice Program).[117]

Aggressive Symptom Management and Palliative Sedation

CASE 6-3

Question 1: D.V., a 35-year-old male with gastric cancer metastasized to the esophagus with periaortic involvement, is hospitalized. He was diagnosed 10 months ago, and his disease has progressed despite multiple courses of chemotherapy. A double-lumen, peripherally inserted central catheter line has been inserted. He has lost 65 pounds (29.48 kg) since diagnosis, weighs 150 pounds (68.04 kg) at 72 inches (182.88 cm) tall, and presents with abdominal pain, severe nausea, vomiting, obstipation (intractable constipation), and general malaise. D.V. describes his pain as a 7 of 10 in intensity and as "burning like a knife through my stomach." He uses 50- to 75 patient-controlled analgesia (PCA) bolus doses every 24 hours. He has no other medical problems. D.V. is referred to hospice care because he and his wife have agreed to stop chemotherapy and do not want to go back to the hospital. He states a history of allergic reactions to morphine, ondansetron, and diphenhydramine, although these reactions are not noted. He is presently receiving hydromorphone 2 mg/hour in an IV infusion with 1-mg PCA bolus dose every 5 minutes, hydromorphone 4 mg orally every 4 hours as needed for pain, fentanyl transdermal 275 µg/hour every 3 days, ketamine 20 mg orally every 3 hours, senna two tablets twice daily, docusate sodium 250 mg twice, PEG 3350 17 g daily, lactulose 15 mL as needed for constipation, lorazepam 2 mg orally every 4 hours as needed for nausea or vomiting, metoclopramide 10 mg orally every 6 hours as needed for nausea or vomiting, ondansetron 4 mg IV every 8 hours as needed for nausea or vomiting, baclofen 10 mg orally every 8 hours as needed for hiccups, and pantoprazole 40 mg orally once daily.

What is your assessment of D.V.'s medication regimen?

D.V.'s drug regimen is unnecessarily complicated for a patient at home. It may be possible to simplify it by looking at each problem anew. His pain is poorly managed as evidenced by his pain intensity

at 7 of 10 (on a scale of 0–10), the use of multiple opioids, and the use of excessive PCA boluses. Once an infusion with PCA dosing is started, there is no need to continue other long-acting opioids (ie, transdermal fentanyl) or oral agents for breakthrough pain. The PCA doses serve as the rescue doses for breakthrough pain, and pain relief should be titrated using this method alone. Once pain is well controlled, an oral long-acting agent can be considered if the patient is able to swallow. To do otherwise creates a chaotic approach. Patients reporting allergic reactions to opioids should be carefully asked to describe the precise nature of the purported allergic reaction. True allergies to opioids are rare; patients often refer to an adverse reaction as an allergy or have experienced an effect from the histamine release that is associated with opioids. Hydromorphone, especially injectable hydromorphone, is much more expensive and no more effective than is morphine and is best reserved for use in patients who cannot tolerate morphine because of adverse effects. Patients who are truly allergic to morphine should be treated with fentanyl or methadone because of the low incidence of cross-reactivity with these agents.

Although D.V. had been prescribed ketamine every 3 hours in the hospital, it is unrealistic to expect that this can be continued in the home setting. D.V. and his wife would probably be glad to discontinue it and replace it with an alternative because of his need to be dosed so often. Discontinuation may result in an exacerbation of pain, and he should be monitored.

D.V.’s constipation is currently treated with multiple medications within the same therapeutic class. It would be more prudent to maximize the use of a single agent within a category, rather than using two products at less than the maximally recommended doses. D.V. can use a higher dose of senna (up to four tablets twice daily), and then, if necessary, continue to use the PEG 3350.[62–65]

D.V. also takes multiple medications for his nausea and vomiting. The serotonin antagonist ondansetron provided as an ODT can be a good option, as an alternative to IV ondansetron. Another good alternative is olanzapine ODT because it provides anticholinergic, anti-dopamine and anti-serotonin activity.[80] He had also been

directed to take lorazepam for his nausea and vomiting; however, benzodiazepines are not effective antiemetics. They are given to manage the anxiety associated with nausea and vomiting and are particularly useful in managing the anticipatory nausea and vomiting that is commonly encountered during chemotherapy administration. Metoclopramide can be useful for D.V.'s nausea and vomiting if his physical examination reveals hypoactive bowel sounds. It is also useful for treating hiccups, and the need for baclofen can be reassessed.

Case 6-3, Question 2: A few days after arriving home, D.V. asks his hospice nurse, "Can't you just give me something to end it all?" He has not been sleeping well, is tired of taking so many medications, and wants to alleviate the burden he feels he is imposing on his wife. How should the hospice nurse respond?

In patients who are terminally ill, suffering may continue despite maximal palliative efforts. As a result, practitioners continually encounter patients' requests for the ending of their lives because of overwhelming suffering. Medical aid-in-dying is legally available in several states, and although substantial numbers of clinicians can imagine situations in which aid-in-dying would be requested, willingness to actively participate in the ending of a patient's life is low.[134–150] A recent literature review did not find any studies examining pharmacists' direct experiences with aid-in-dying.[151] Nonetheless, pharmacists should be aware of and understand issues around the practice. The NHPCO has developed comprehensive resources, the LAD (Legally Accelerated Death) Series, for clinicians.[152] The State Information document contains links to state statutes and statistics, organizational policy statements (including ASHP's), and provides a bibliography.[153] In a small number of patients, it may be desirable to reduce suffering by the thoughtful use of medications to induce light to moderate sedation.[154–157] Unlike aid-in-dying, the intent of palliative sedation is to relieve suffering, not to hasten death. Death may, however, result as an unintended consequence of escalated drug dosing, as a

double effect. Data is lacking on the effect of palliative sedation on quality of life and survival following this intervention, and patients may continue to experience pain, dysphoria, or other adverse events.[158,159] Palliative sedation should only be initiated as a last resort in severe cases not responsive to other palliative measures, and only after thorough discussion of the important clinical and ethical issues with the patient, family, and other clinical team members.[160–162]

Medications used successfully to induce sedation for these patients include benzodiazepines, barbiturates, and propofol, generally given in combination.[163] The goal is to attain light to moderate sedation to preserve the airway. Opioids are continued to manage pain and prevent withdrawal. A best practice is to develop organizational policies, standardized orders, and quality assurance monitoring.[164] A trial of palliative sedation with IV midazolam could be initiated and managed by the hospice nurse at a rate of 1 mg/hour and gradually increased if needed to the desired effect.[163] For use in the home, crushed phenobarbital tablets administered via a rectal catheter could be added if the desired effect is not attained with midazolam alone.[165] Use of other agents such as propofol and dexmedetomidine are best reserved for use in inpatient settings.

Before considering palliative sedation, patients should be thoroughly assessed for insomnia, depression, pain, and other symptoms. Underlying reasons for insomnia should be explored and treated. Poor pain management is often the cause for considering palliative sedation. As many as 10% to 20% of patients with cancer may have pain that does not respond to standard systemic analgesics.[166] Interventional techniques, including the administration of spinal opioids and/or local anesthetics may be useful, but may not be practical to initiate for the actively dying patient at home.[167–169]

Case 6-3, Question 3: Repeated increases in the hydromorphone infusion basal rate (he is now at 25 mg/hour) had little effect on managing D.V.'s pain, and his consistent use of up to 120 PCA attempts in 24 hours reflects his continued pain. He describes the intensity of his pain as 8 of 10. Before

considering palliative sedation, what other therapeutic interventions can be implemented for D.V.?

In D.V., lidocaine 0.5 to 1 mg/kg/hour administered IV or subcutaneously might be useful to assist in the management of his severe neuropathic pain.[170–173] Lidocaine purportedly interrupts pain transmission by blocking sodium channels (see Chapter 55, Pain and Its Management). D.V. was started on lidocaine 1 mg/kg/hour IV. A bolus dose was not given because of the short half-life of lidocaine. Overnight, his use of hydromorphone boluses dropped to one. He now reports his pain as 1 of 10 and that he slept through the night for the first time in months. During the next 2 days, the hydromorphone basal rate was tapered to 5 mg/hour. He did not experience any lidocaine toxicity, such as perioral numbness, metallic taste, or somnolence. D.V. continued on lidocaine, using no hydromorphone boluses for the next 2 weeks, until he died at home surrounded by his family.

Interprofessional Practice and Education

Michael G. Carvalho, Edith Claros, Christopher K. Cooper, and Kaelen C. Dunican

CORE PRINCIPLES		CHAPTER CASES
1	The Interprofessional Practice and Education Collaborative (IPEC) produced an original report with a 2016 update developed by an expert panel that established four core competencies of interprofessional practice and education (IPE): (a) values and ethics for interprofessional practice; (b) roles and responsibilities; (c) interprofessional communication; and (d) teams and teamwork.	**Case 7-1 (Question 1)** **Case 7-3 (Questions 1–5)**
2	The IPEC report considers communication a key competency. Unfortunately, this can be negatively	**Case 7-2 (Question 1)**

	impacted by demographic and professional differences that may exist between health care professionals. To address this issue, the IPEC report encourages all team members to be willing to speak up in a respectful way if they have a patient-related concern.	
3	Although one should understand what IPE is, it is also important to clarify what does not constitute IPE. Experiences on Advanced Pharmacy Practice Experience (APPE) rotations that are directed by someone from another profession that do not include sharing of responsibility for patient care are not considered IPE.	**Case 7-4 (Question 1)**
4	One element of an IPE model is understanding that different professions may vary in how they approach patient care. Team-based care means a shared responsibility for patient care on the part of all team members and should not be dominated by any one profession. IPE models can take place in a variety of settings, such as a classroom, laboratory, and a patient care setting. Regardless of the environment, IPE-related activities should represent a “real-world” experience.	**Case 7-5 (Question 1)**
5	Incorporating IPE in the pharmacy curriculum should involve early exposure to enhance students’ confidence in their professional value,	**Case 7-6 (Question 1)** **Case 7-7 (Questions 1, 2)**

	support their respecting the contributions of other professions, and better prepare them for providing team-based patient care. These early IPE experiences also increase the appeal of collaborating with other professions, reduce any negative stereotypical attitudes toward these other professions, and strengthen communication skills.	
6	The Health Professions Accreditors Collaborative (HPAC), in association with the National Center for Interprofessional Practice and Education (National Center), provided a guidance document on developing quality interprofessional education for the health professions. They stated that IPE plans should include four characteristics: (a) a rationale; (b) outcome-based goals; (c) a deliberate design; and (d) assessment and evaluation.	**Case 7-7 (Questions 3, 4)**

INTRODUCTION

Interprofessional practice and education (IPE) is a concerted effort to prepare medical, pharmacy, nursing, physician assistant (PA), and other health profession students to collaborate and deliver patient care as part of a team.[1] In the early 1970s, the Institute of Medicine (IOM) report “Educating for the Health Team” addressed pharmacy as a component of the team as well as medicine, nursing, and

dentistry.[2] However, there remains a concern that many practitioners, including pharmacists, are commonly trained in programs that are removed from other health care professionals. This educational separation could potentially have a detrimental effect on the beliefs and values that these practitioners may have on the contribution of other providers to patient care.[3,4] In 2003, the IOM addressed this matter in its report "Health Professions Education: A Bridge to Quality."[5] The report stressed incorporating interprofessional experiences into health care education and establishing core competencies for IPE. The 2003 IOM report states "all health professionals should be educated to deliver patient-centered care as members of an interprofessional team, emphasizing evidence-based practice, quality improvement approaches, and informatics."[5] These IOM recommendations generated the momentum for health professions to advance the need for IPE.[1,4] It is evident that with the increasing prevalence of chronic diseases and the complexities of delivering health care today, an interprofessional approach toward patient care is important.[3] In addition, new approaches to health care have stimulated a movement toward team-centered health care, such as the patient-centered medical home (PCMH) concept that encourages interprofessional teamwork in providing primary care.[6] With the PCMH model, physicians share responsibility with nurses, pharmacists, social workers, and others to manage complex patient care cases. The PCMH model puts the patient at the center of his/her health care and expands access and improves mechanisms for patient–provider communication, including the use of technology for patients to interact with their health care provider and have access to other health care resources.[6]

The evolution of an IPE model that incorporates collaborative practice along with fundamental and continuing interprofessional education is referred to as the *new IPE*.[7] This is a way to create a shared space between interprofessional education, interprofessional practice, and collaborative practice to improve health care outcomes while reducing cost.[7] Thus, IPE is crucial in establishing integrated interprofessional teams that provide patient- and family-centered care to achieve what the Institute for Healthcare Improvement has

termed the *Triple Aim*.[8] In this model, the three dimensions of care are to (a) improve the patient experience of care, (b) improve the health of populations, and (c) reduce the per capita cost of health care. More recently there has been an expansion to a fourth goal: (d) of improving the work life of health care providers including clinicians and staff.[9] This "Quadruple Aim" recognizes "provider burnout" as an impediment to effective health care that needs to be addressed. Interprofessional patient care could potentially reduce individual caregiver burden and enhance each team members' sense of contributing to shared outcomes.

CORE INTERPROFESSIONAL EDUCATION COMPETENCIES

CASE 7-1

QUESTION 1: You are enrolled in an IPE seminar with pharmacy, nursing, PA, and medical students. Each week you will be assigned cases to work on in groups.

Your initial impression is that these exercises are primarily designed to help foster teamwork, but are there any other areas that IPE helps develop as well?

The Interprofessional Practice and Education Collaborative (IPEC) was formed in 2009 from six national associations of schools of health professions (dentistry, medicine, nursing, osteopathic medicine, pharmacy, and public health), to promote joint efforts to advance interprofessional learning experiences with the goal of helping prepare students to participate in team-based patient care. An expert panel from its members produced a report in 2011 that established Core Competencies for Interprofessional Collaborative Practice.[10] In 2016, IPEC published an update that organized and broadened the competencies within the domain of interprofessional collaboration to better achieve the Triple Aim with an emphasis on

population health.[11] A subsequent update is currently being developed and is due to be released in early 2023.[12]

The far-reaching impact of IPEC on health education since its inception has been demonstrated by the addition of associations of other health professions to its original core group including nutrition and dietetics, PA, podiatry, respiratory care, physical therapy, occupational therapy, psychology, speech-language and hearing, chiropractic medicine, optometry, veterinary medicine, and health library science.[13]

The four IPEC competencies are (a) values and ethics for interprofessional practice, (b) roles and responsibilities, (c) interprofessional communication, and (d) teams and teamwork.[10,11] These competencies were identified to create a coordinated effort across the different health care professions to incorporate key content into their respective curricula and to guide curricular development. The competencies also provide a foundation for lifelong learning, as well as offer information to the different professions' educational program accrediting bodies that can be used to set common accreditation standards.[10,11,14]

In the first competency, IPEC considers interprofessional values and ethics as important elements in establishing a professional and interprofessional identity. These values and ethics are patient centered and grounded in a shared purpose to provide compassionate patient care. Working in teams adds value to patient/family and community outcomes that promote overall health and disease prevention beyond just the more traditional treatment of disease. In addition to being patient centered, competency in this area helps develop trusting relationships with patients, families, and other members of the health care team. There is also an expectation that one maintains competency in one's own profession relative to his/her area of practice.[10,11]

The second competency addresses the importance that IPEC places on one's understanding of how professional roles and responsibilities complement each other in providing patient care to advance the health care needs of patients and populations. It is this diversity of expertise that is the foundation of an effective health care

team. Coordination of care occurs more effectively when each profession knows what the other can contribute to patient care.[11] Pharmacists should be able to effectively articulate to other team members what they can contribute in executing a treatment plan, especially when it comes to preventing and identifying any drug-related problems. Sharing roles has also been shown to enhance patient outcomes and reduce costs.[3] For example, a nurse, social worker, and pharmacist can collaborate to develop a discharge plan that reduces the potential for hospital readmission by addressing such issues as community resources that may be available for assistance, medication adherence, patient education, and health care provider follow-up.[3] The IPEC documents note that one should also understand the limitations of one's abilities, knowledge, and skills and engage in continuous interprofessional development to improve team performance.[10,11]

IPEC places communication as the third key competency. The expert panel states that one should communicate with patients, families, and both health care and non–health care professionals in a responsive and responsible manner. Characteristics such as being available, being well-informed, showing interest, and being receptive are key aspects of this communication area as well. Listening and encouraging the input of other members are also important attributes for this competency. Presenting information in a manner that patients, families, and other team members can understand helps enhance the safety and effectiveness of interprofessional care.[10,11]

CASE 7-2

Question 1: You are a pharmacy student on your Advanced Pharmacy Practice Experience (APPE) rotation in internal medicine participating in medical rounds with a medical team that includes a very intimidating attending physician. Your team is evaluating a patient presenting with an upper respiratory tract infection. You note from the medical record that the patient is on warfarin. The attending physician directs the medical resident to order an antibiotic that you know may interact with warfarin and possibly increase the risk of bleeding.

How should you communicate your concerns to the attending?

Communication can be negatively impacted by demographic and professional differences that may exist between health care professionals (eg, older attending physician and younger pharmacist). To address this issue, the IPEC report encourages all team members to be willing to speak up in a respectful way if they have a patient-related concern. You should politely and very clearly explain to the attending what your concern is and provide evidence-based literature to support the nature and severity of the interaction. Despite the attending's intimidating demeanor, failure to communicate the problem could result in harm to the patient. Being able to provide and receive feedback with confidence helps promote team-based care.[10,11]

The fourth competency of IPEC, teams and teamwork, means working together for common patient care goals. Working in teams not only relates to shared problem-solving but also being able to constructively manage any disagreements that arise with other health care professionals as well as patients and family. Conflicts may occur when power is confused with expertise based on professional background. Staying focused on patient outcome and addressing any potential conflict openly through shared problem-solving and utilizing effective communication skills can help establish a more effective team. Besides, the report indicates that working in teams also means giving up some professional autonomy. Health care teams function best when the knowledge and expertise of the different professions on the team are integrated to make better patient care decisions.[10,11]

As a consequence of this shift toward teamwork, most health care profession–accrediting organizations, including pharmacy, nursing, and medicine, now incorporate interprofessional collaboration and teamwork as part of their standards.[14] In fact, the Health Professions Accreditors Collaborative (HPAC), consisting of many of the accrediting bodies of professions that are part of IPEC, was founded in 2014 in part to help facilitate the incorporation of intentional IPE throughout the curricula of its member bodies.[15] The basic principle of IPE is that if students from different health care professions learn

together, they will be better positioned to work together in teams to provide optimal patient care.[11]

CASE 7-3

Question 1: A.Z. is a 66-year-old female, mother of six, widowed, non–English-speaking Muslim refugee with limited medical literacy, who comes to urgent care with a 3-day history of cough and fever. You are an ambulatory care pharmacist working with the medical team responsible for the care of A.Z. that includes a bilingual (English to Arabic) translator, nurse practitioner, nurse, physician, PA, and social worker. Her medical history includes type 2 diabetes mellitus, hypertension, hyperlipidemia, posttraumatic stress disorder (PTSD), and anxiety. She takes metformin 1000 mg twice a day, simvastatin 20 mg daily, lisinopril/hydrochlorothiazide (HCTZ) 10 mg/12.5 mg daily, and clonazepam 0.5 mg three times a day as needed. A.Z. is accompanied by her eldest son who translates for her and guides the medical decision-making process. A.Z. and her children practice traditional folk remedies such as black seed oil for respiratory problems and honey for diabetes. A review of A.Z.'s vital signs and laboratory work indicates that her blood pressure is 166/88 mm Hg, preprandial blood glucose is 210 mg/dL, and total cholesterol is 220 mg/dL.

How can we address each of the IPEC core competencies regarding this case?

Values and Ethics

Case 7-3, Question 2: To respect A.Z. and her family's cultural beliefs while delivering high-quality and effective health care, what aspect of the care plan can be customized to ensure this patient receives care that reflects the patient's values?

Patients of different cultures and religions may experience conflicts regarding their values or morals when interacting with members of the health care team. Health care providers' awareness of and sensitivity to such issues can benefit patients and increase the quality of care they receive. It is important to understand the religious implications, culture, family perspectives, health practices, and beliefs of people of the Islamic faith. It is also important to validate the patient's use of home remedies and work together to

incorporate as many cultural practices as possible. Creating and maintaining clinical relationships based on trust and good communication is essential. Protecting the patient's freedom of belief, and maintenance of life and intellect while preserving honor and integrity is paramount in the Islamic faith.[16]

The team should be cohesive in its approach to maintain a climate of mutual respect and shared values between team members as well as with patients and their families.

Roles and Responsibilities

Case 7-3, Question 3: You use your knowledge of your own role and those of other professions to appropriately assess and address A.Z.'s health care needs and the needs of her family to promote health and well-being. How does the pharmacist's approach differ from that of the other team members?

The pharmacist can explain to the family the medication regimen prescribed for the patient and discuss the rationale for treatment while being mindful of her cultural background. Prescription records can be reviewed for evidence of validating adherence. The pharmacist could research and provide information to the rest of the team on the herbal remedies that A.Z. is using. These home remedies can be explored for potential interaction with the prescribed medication (eg, how is the cultural use of "honey for diabetes" potentially affecting her treatment and could its judicious use be incorporated into her treatment regimen). The pharmacist's knowledge of dietary supplements could also be helpful in suggesting alternative treatments that may be culturally acceptable to the patient and family.

The nurse practitioner or PA could initiate, manage, and coordinate A.Z.'s health care needs with the interdisciplinary team. Tasks will include, but not be limited to, prescribing medication, assessing efficacy of current medication and treatment plan, educating the patient and family about current treatment modalities, health promotion, and harm reduction. The primary care provider

(physician, PA, or nurse practitioner) can consider a referral to a mental health professional for counseling and mental health treatment as indicated. Other team health care members such as the social worker could assess how the patient's PTSD and the role of the family dynamics could be affecting her health and treatment. A nutritionist could be helpful in assessing and addressing her dietary requirements in the context of her cultural orientation.

Communication

Case 7-3, Question 4: A.Z.'s son tells you in confidence that his mother does not take any of her medications because the family uses home remedies. Should you communicate this information to the rest of the team and, if so, how would you do it?

It would be important to discuss with the son the need to share any vital information that could affect his mother's health and well-being with the team. Explain to the son that his mother is an integral part of the team and is, in fact, its *center*. As such, she will not be ostracized by the team; rather, her actions and beliefs will be taken into consideration and become a part of the team plan. Communicating with the patient and her son about the role of medications is a necessary part of the teaching process. Being open to patient/family questions or concerns is crucial. Complete and open communication with the rest of the interprofessional team is essential for quality and consistency of care.[17]

Teams and Teamwork

Case 7-3, Question 5: The pharmacist, translator, mental health care nurse practitioner, nurse, physician, PA, and social worker meet with A.Z. and her children as part of care planning, delivery of care, and discharge. What teamwork skills are necessary to deliver patient-centered care that is safe, timely, efficient, effective, and equitable?

Teamwork skills include communication, problem-solving, listening, self-awareness, and collaboration. These are essential for providing quality health care. Effective team skills can improve patient outcomes, prevent errors, improve efficiency, and increase patient satisfaction. It is important to establish at the onset of care how patients and families want to be involved in their care. Engaging them in designing their plan of care increases their understanding of tests, procedures, and anticipated care outcomes, ensuring a successful discharge. Each member of the team contributes, within the confines of their own specialty, the needed skills to optimize the patient's health and clinical care.[18]

This unified approach achieved through the blending of multiple disciplines, with the patient and family at its center, is the key to a successful interprofessional team.

The end game of IPE is to establish and support fully functioning interprofessional teams that collaborate to promote the Quadruple Aim[9] to optimize effective, compassionate, and cost-effective patient/community care while validating caregiver knowledge, skills, and teamwork. The IPEC core competencies can be seen not only as goals of preprofessional training but also as a grounding in the learning continuum of team members throughout the practice trajectory (**Fig. 7-1**).[11]

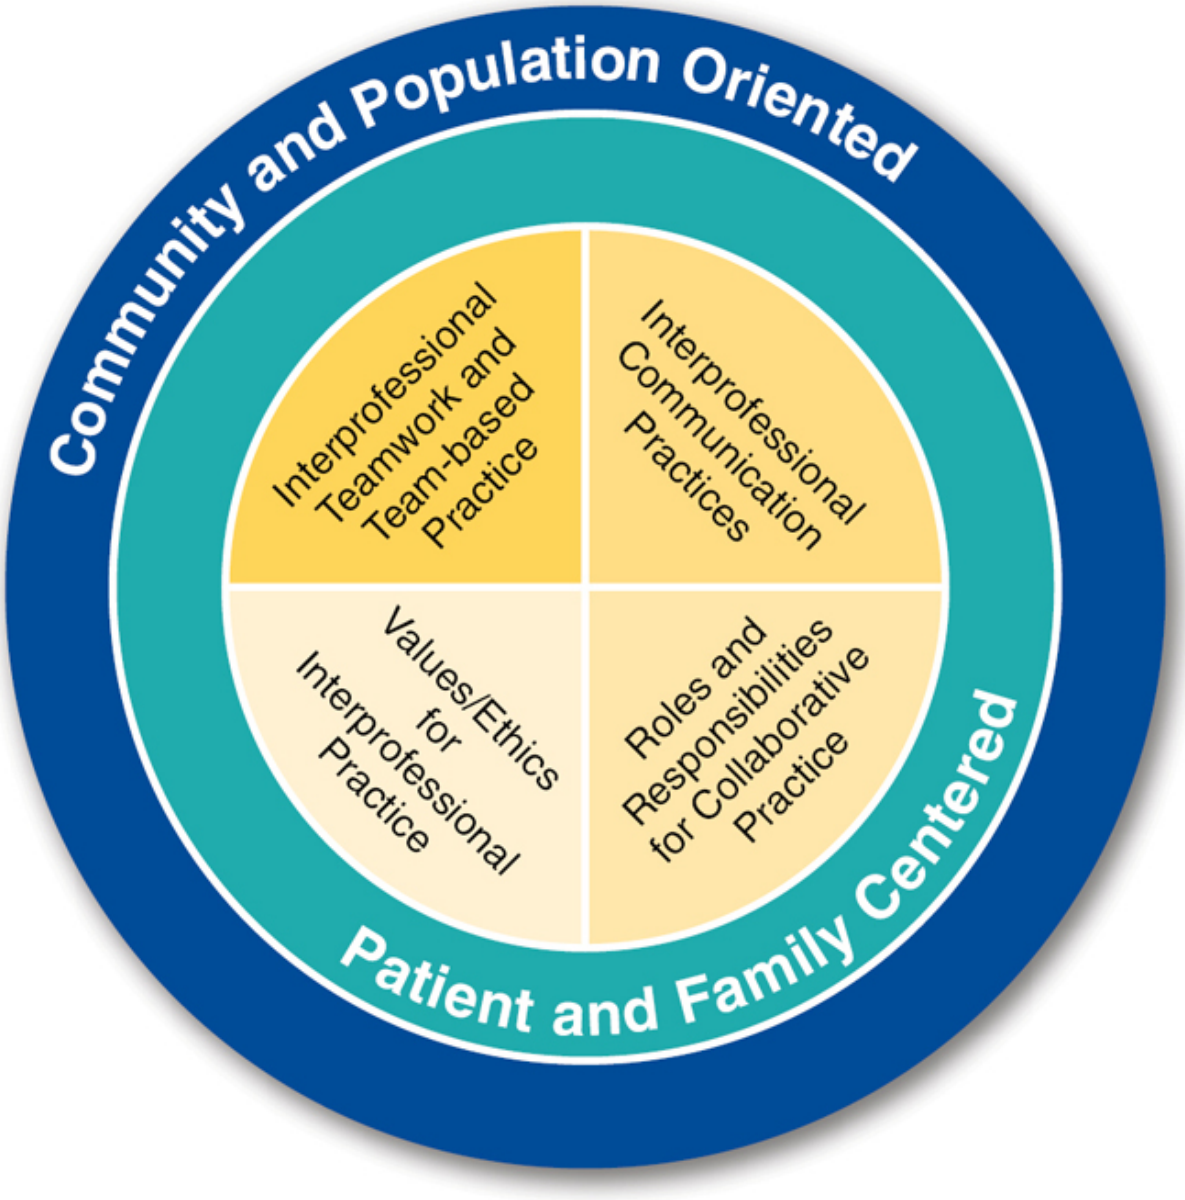

Figure 7-1 Interprofessional collaboration competency domain. (Source: Interprofessional Education Collaborative. Core competencies for interprofessional collaborative practice: 2016 update. Interprofessional Education Collaborative. 2016. Accessed April 5, 2022. https://ipec.memberclicks.net/assets/2016-Update.pdf. Reprinted with permission from Association of American Medical Colleges.)

INTERPROFESSIONAL EDUCATION TERMINOLOGY

The terminology related to IPE can be confusing because meanings of "multidisciplinary," "interdisciplinary," and "interprofessional" may differ in the literature.[4] The former terms describe a simple and additive approach to patient care, with several health care providers providing independent services and each responsible for their own specialty. As described earlier, IPE is a more coordinated approach in which there is an integration and collaboration to include the viewpoints of many different professions to optimize patient care.[4]

To help clarify and standardize interprofessional terminology, HPAC has compiled a consensus table (**Table 7-1**).[14]

Table 7-1
Consensus Terminology in the Published Literature

Term	Definition	Organization
Interprofessional education	"When students from two or more professions learn about, from and with each other to enable effective collaboration and improve health outcomes."	WHO[a]
Interprofessional collaborative practice	"When multiple health workers from different professional backgrounds work together with patients, families, carers[b], and communities to deliver the highest quality of care."	WHO[a]
Interprofessional teamwork	"The levels of cooperation, coordination and collaboration characterizing the relationships between professions in delivering patient-centered care."	IPEC[c]
Interprofessional team-based care	"Care delivered by intentionally created, usually relatively small work groups in health care who are recognized by others as well as by themselves as having a collective identity and shared responsibility for a patient or group of patients (e.g., rapid response team, palliative care team,	IPEC[c]

	primary care team, and operating room team)."

CASE 7-4

QUESTION 1: You are on an internal medicine APPE rotation and on rounds with a patient care team that includes a medical student, nursing student, and dietetics student. The medical resident presents a case of an elderly patient recently admitted with worsening heart failure and determines what the treatment plan would be without involving anyone else on the team.

Is your experience considered an example of IPE?

Although one should understand what IPE is, it is also important to clarify what does not constitute IPE. For example, students from different health professions learning the same topic in a classroom setting (eg, pharmacology) without interacting and discussing the material as it pertains to their respective discipline are not considered IPE.[4] Nor is it IPE when a faculty member from another profession lectures pharmacy students unless that person incorporates some component on how the professions would interact in providing patient care.[4] Also, experiences on APPE rotations that are directed by someone from another profession that do not include sharing of responsibility for patient care are not considered IPE.[3] Consequently, the experience described in Case 7-4, Question 1, is not considered IPE. Clearly, the underlying theme of any IPE activity is that it should be a collaborative effort of students representing different professions.

INTERPROFESSIONAL EDUCATION MODELS

The creation of an effective model for IPE should start with the understanding that this is just the initial step in providing patient-directed care.[3] An interprofessional environment helps students from one profession learning from individuals representing another discipline to better develop skills that will help improve their own profession-specific skills and to more effectively work in a team-based setting.[3] There also needs to be a commitment that IPE be incorporated within the curricula of all programs within an institution to help sustain its future viability.[3] In addition to other health profession students, pharmacy students should be considered essential to any IPE model. As the practice of pharmacy has evolved into more of a patient-focused, clinically oriented dynamic, pharmacy students must be able to step into frontline roles with other health professional students who have had a tradition of “hands-on” patient care.

Outreach to other institutions that educate important health care students critical to the IPE team, such as medicine, dentistry, and social work, will become necessary. This requires communication, shared planning and training, and, ultimately, formal agreements among institutions to participate in IPE.

The stage of socialization within the specific profession must be considered when creating interprofessional teams as well.[3] Socialization of health care students has been defined as “the acquisition of knowledge, skills, values, roles and attitudes associated with the practice of that particular profession,” and can be exhibited by the language, behavior, and demeanor that are representative of that specific discipline.[3] It is important that students maintain their professional identity when participating in an IPE model. When creating student teams, one should try to balance them regarding where they are in their professional education and socialization.[3] Medical students who are in the fourth year of their program paired with less experienced health care students may

negatively impact the learning of other students if the medical student assumes a more dominant role.[3]

CASE 7-5

Question 1: M.M. is a 65-year-old retired male who presented to his provider 3 days ago with reporting increased shortness of breath (dyspnea) upon exertion. He reports noting swelling in his ankles for months that has started to get worse over the past 2 weeks. This is making it difficult to go up the stairs to his apartment and to wear his shoes toward the end of the day. In the past week, he has had a decreased appetite, nausea and vomiting, and tenderness in the right upper quadrant of the abdomen. He reports that he has not taken his medications in the past month because he did not think they were helping him. The patient lives alone with his dog in a small two-bedroom apartment on the second floor of a multifamily home. He has a daughter who lives in another state and who visits him during the holidays. The patient was hospitalized and treated for a diagnosis of exacerbation of congestive heart failure (CHF) and is now being discharged home. A physician, PA, nurse, social worker, and pharmacist are part of a discharge planning team working with M.M.

How does the approach of the pharmacist to M.M.'s care differ from that of the other team members?

One element of an IPE model is understanding that different professions may vary in how they approach patient care. Medicine and pharmacy tend to focus on eliminating or "ruling out" causes of a patient's patient's reported symptoms, whether it is medical or drug related.[3] Although the physician or PA may focus primarily on the medical evaluation of M.M., the pharmacist would determine whether any of his medications were causing effects that may have contributed to his belief that they were not helping him. The pharmacist would also work with M.M. to develop a plan that would enhance adherence to his discharge medications. Some other members of the team, such as the nurse and social worker, may take a more holistic approach and address the patient from a broader perspective.[3] This would include considering any family or environment issues that may affect M.M.'s progress such as ability for self-care when living alone and not having a relative living close by. They could plan to make sure that M.M. has the proper support at home. The nurse can also educate the patient about the

importance of adherence to proper diet and to recognize early signs and symptoms of exacerbation. Some professions such as social work or psychology tend to be more involved with the patient or family for a more prolonged period of time, particularly if a change in behavior is warranted.[3] Another consideration with how different professions approach patient care is that medical students are typically trained to be decision-makers regarding clinical problem-solving, which has been a long-standing part of the culture of medicine.[19] As noted previously, team-based care means a shared responsibility for patient care on the part of all team members and should not be dominated by any one profession.

INCORPORATING INTERPROFESSIONAL EDUCATION INTO THE CURRICULUM

CASE 7-6

QUESTION 1: In your first professional year in pharmacy school, you are in an introductory health care seminar course with other health profession students. A fellow classmate shares that she would prefer to be with only other pharmacy students until later in the curriculum.

What are the possible benefits of having other health care students in an introductory-level course?

The goal of IPE is to develop knowledge, skills, and attitudes that result in interprofessional team competence.[10] This includes not only clinical skills but also communication, conflict resolution, and team building skills, in addition to respecting the roles and responsibilities of other health professions.[3] IPE is best when it is incorporated throughout the entire curriculum in a vertically and horizontally integrated manner, in which collaboration, teamwork, and patient-centered care are introduced to students before their entering the professional phase of the curriculum.[10] It has been reported that early exposure to the IPE approach enhances students' confidence

in their professional value, supports their respecting the contributions of other professions, and better prepares them for providing patient care.[20] It has additionally been noted that early educational experiences within an IPE program increase the appeal of collaborating with other professions, reduce any potential negative stereotypical attitudes one may have toward these other professions, and enhance communication skills regardless of any specialized knowledge one may have.[21]

The American Council for Pharmacy Education (ACPE), the pharmacy education accrediting body, included IPE in Standard 11 of their 2016 Standards and Guidelines for Accreditation.[22] To meet this standard, the PharmD curriculum "should prepare all students to provide entry level, patient-centered care in a variety of practice settings as a contributing member of an interprofessional team. In the aggregate, team exposure includes prescribers as well as other healthcare professionals."[22] Pharmacy schools must develop an interprofessional education plan throughout the didactic and experiential portions of the curriculum applying to all students in a variety of practice settings.

The key elements of this standard include interprofessional team dynamics, interprofessional team education, and interprofessional team practice that incorporate all the IPEC core competencies. The interprofessional dynamics section of the standard addresses values and ethics, interprofessional communication, conflict resolution, and honoring interprofessional roles and responsibilities. The standard indicates that "these skills should be introduced, reinforced, and practiced in the didactic and Introductory Pharmacy Practice Experience (IPPE) components of the curriculum, and competency is demonstrated in the Advanced Pharmacy Practice Experience (APPE) settings."[22]

The interprofessional team education component includes "opportunities for students to learn about, from, and with other members of the interprofessional health care team. Through interprofessional education activities, students gain an understanding of the abilities, competencies, and scope of practice of team members."[22]

The team practice section mandates that "all students competently participate as a healthcare team member in providing direct patient care and engaging in shared therapeutic decision-making." They all should "participate in experiential educational activities with prescribers/student prescribers and other student/professional healthcare team members, including face-to-face interactions that are designed to advance interprofessional team effectiveness."[22]

In January 2018, the ACPE Board added the additional guidance that the expectation for IPE experiences in both the didactic and experiential components of the curriculum would include prescribers/student prescribers with the "mix of prescribers to include (but is not limited to) physicians and their students in both the didactic and experiential components of the curriculum."[23]

INTERPROFESSIONAL EDUCATION GUIDANCE DOCUMENT

As more health professions accrediting bodies have mandated IPE activities in their respective training programs, there has been a movement to provide more guidance to ensure the quality and viability of these programs. Quality IPE training also helps develop collaborative practice teams that will proliferate and become a model of patient care to help promote better population health. The National Center for Interprofessional Practice and Education (National Center) is a public/private partnership housed at the University of Minnesota that was founded in 2012 to "provide the leadership, evidence and resources needed to guide the nation on the use of interprofessional education and collaborative practice to enhance the experience of health care, improve population health and reduce the overall cost of care."[7]

The National Center collaborated with the HPAC to release its Guidance on Developing Quality Interprofessional Education for the Health Professions in 2019.[14] The goals were to "facilitate the

preparation of health professional students for interprofessional collaborative practice through accreditor collaboration and to provide consensus guidance to enable institutions to develop, implement, and evaluate systematic IPE approaches and IPE plans."[13]

The document recommends that quality IPE plans include the following characteristics: (a) a rationale; (b) outcome-based goals; (c) a deliberate design; and (d) assessment and evaluation. The rationale should articulate a vision, framework, and justification for the IPE plan. Outcome-based goals should be achievable by students to demonstrate interprofessional competencies for collaborative practice. A deliberate design of the IPE plan should incorporate a variety of intentional interprofessional activities that are integrated longitudinally into the entire length of the curriculum and demonstrate achievement of the outcome-based goals appropriate for the level of the learner. The assessment and evaluation process should quantify the students' proficiency in interprofessional competencies throughout the curriculum and serve as an evaluation of the institutional IPE plan for quality improvement.[14]

CASE 7-7

QUESTION 1: Your school of pharmacy would like to incorporate a foundational IPE activity into the didactic curriculum.

How should planning be initiated for an activity involving students from multiple health care professions?

As mentioned previously, IPE must be incorporated into the pharmacy curriculum for all students throughout the length of the curriculum to meet ACPE accreditation standards.[22]

The HPAC/National Center guidance document[14] will function as a blueprint in the development of the rationale, outcome-based goals, deliberate design, and the assessment/evaluation of the proposed activity.

The overall IPE curricular plan must be considered when designing the first activity because subsequent programming will continue to build upon this foundation. An interprofessional team is

vital for successful development of any IPE activity in academia. Faculty and staff are most often the activity developers. Each student profession targeted to participate in the activity should be represented on the faculty/staff development team and this team must agree on an activity that will benefit all participants. As mentioned earlier, participating students should be at similar levels within their professional education. Faculty and staff who value IPE and interprofessional collaboration are best suited for the development team as opposed to assigned participation by a department chair/supervisor. Having student members on the development team is extremely beneficial. Students can provide a reality check for what is being expected of the participants during the activity and the level of knowledge/skills of the activity participants.

The focus of the activity must be linked to one or more of the IPEC core competencies,[11] and specific, measurable objectives must be developed. Each objective should then correspond with an assessment method that will allow evaluation of students' achievement. An interactive component is essential for any IPE activity because students should be learning about, with, and from each other. The quality of an IPE activity is dependent on the quality of the student interaction. Careful consideration needs to be given to the type of interaction that can reasonably fit within the timeframe of the activity. Examples of interactions include patient case discussions, group assignments, role-play, and simulation.

Case 7-7, Question 2: The interprofessional development team will develop an IPE activity that will involve pharmacy students and several other health care profession students that are local to the School of Pharmacy. What are additional considerations for the team?

Scheduling is often the rate-limiting step for any IPE activity. The challenge of making sure that the activity is part of the curriculum requires that there is synchronization within all professional curricula to allow for interprofessional education. There should be buy-in from upper administration as well as close cooperation between the administrative faculty and curriculum committees of each

representative health profession. It is vital that the members of the IPE development team communicate with their respective faculty so that there is an opportunity for the recruitment of ideas and preceptors to assist in the activity.

The ACPE requirement for involvement with "physicians and their students" in IPE activities would require agreements with area medical schools and coordination with their respective IPE leaders to participate in IPE programs. It may be easier to engage medical programs that are housed in the same university setting as the pharmacy schools, but more difficult if there is a logistical or cultural divide between the two professional schools. Medical schools are under the same accreditation pressure to include IPE into their curriculum, so it is imperative that pharmacy IPE leaders become proactive in promoting the need for pharmacy students/faculty in the mix for joint IPE activities.

Virtual, online platforms such as Zoom may allow more flexibility with scheduling and would eliminate any constraints due to physical space for large group gatherings.

Another consideration is what students already know about IPE before the activity. Has IPE been introduced within each profession's curriculum and has consistent terminology been used? If not, introductory information on IPE will need to be discussed at the start of the activity. The IPE planning team must also decide on the deliverables of the activity. Will the students be required to submit prework of any kind? Will there be a group assignment, and would it include a graded component? Weighting of graded assignments should be balanced for all participating students to encourage a consistent level of effort. A discussion of the value of IPE and a joint show of support from the interprofessional planning team should also precede the program.

Case 7-7, Question 3: The interprofessional development team would like to design an introductory IPE activity that will focus on two IPEC competencies: interprofessional communication and roles/responsibilities. How might this IPE activity be implemented?

An example of an introductory roles and responsibilities IPE activity that has been implemented in various schools of pharmacy centers on a simple checklist of health professionals' routine tasks. This 60- to 90-minute activity begins with students independently completing a checklist of professional activities performed by various health care practitioners. Examples of items on the checklist include "Administer immunizations" and "Prescribe scheduled medication." The checklist instructions ask students to indicate which items fall within the scope of practice for an entry-level practitioner from each of the participating health care programs. Students then work together in interprofessional teams to complete the checklist a second time with the goal of identifying activities that are similar (applying to all the health care practitioners) and activities that are unique to each profession. Interprofessional teams of 8 to 10 students are preassigned to ensure that students are engaged with all other programs. Facilitators include faculty (health care professionals) from each of the programs involved. This IPE activity exposes pharmacy students to the roles and responsibilities of their own profession as well as those of the other professions. It is also the first opportunity for pharmacy students to interact and communicate with students from other programs within a required course. This activity can be presented in both live (in person) or via a virtual (Zoom) format.

This IPE activity includes three outcome-based objectives: (a) communicate one's roles and responsibilities to an interprofessional group; (b) identify unique and similar responsibilities among health care professionals; and (c) explain how the interprofessional team works together to provide patient care. This initial IPE activity is ideal for first-year students because it sets a foundation for the overall IPE plan. The framework for the IPE curriculum should be deliberately designed to build in breadth and depth with more case-based, clinical activities as the didactic/clinical curriculum progresses.

CASE 7-7, QUESTION 4: How is the activity assessed?

The activity concludes with an evaluation based on the session objectives and overall rating of the activity. There are also a variety of IPE assessment scales that have been published that can be utilized to assess student attitudes and achievements of competencies in IPE.

The Readiness for Interprofessional Learning Scale (RIPLS)[24] and the extended RIPLS[25] are two well-established tools for assessing interprofessional attitudes, but these were developed before the establishment of the IPEC core competencies. The more recent Interprofessional Attitudes Scale (IPAS)[26] is a validated 27-item scale that links IPE assessment to the IPEC core competencies. This scale can be completed by participants in 10 minutes and has been given pre- and postactivity to measure changes in IPE attitudes. The Student Perceptions of Physician-Pharmacist Interprofessional Clinical Education (SPICE) instrument was developed to specifically measure changes in the perceptions of medical and pharmacy students after IPE activities.[27] Elimination of profession-specific language in SPICE-Revised allowed this instrument to be used across all health professions.[28] Further refinement and validation of this tool resulted in the appearance of the most recent SPICE-R 2.[29]

The IPEC Competency Self-Assessment Tool[30,31] was designed to allow students to self-assess their progress on items linked to the 42 subcompetencies of the IPEC core competencies. This validated tool can be administered periodically throughout the curriculum (eg, at each year's baseline and at end of each year) to help monitor the progression of developing IPE competencies.

These and other IPE assessment tools can be accessed on The National Center for Interprofessional Practice and Education website, which maintains an updated Measurement Instrument Collection at https://nexusipe.org/advancing/assessment-evaluation.

INTERPROFESSIONAL EDUCATION: FUTURE DIRECTIONS AND RESOURCES

To sustain the IPE momentum that has developed over the past several years requires the necessary resources to support it, both at the academic and professional levels.[32] Further opportunities for collaboration between professions need to be identified, and health care education needs to advance to the point where interprofessional team–based learning becomes the norm.[33] Quality academic and clinical research needs to demonstrate that interprofessional collaboration results in the advancement of the Quadruple Aim.[34] Functional interprofessional teams need to be developed, fostered, and supported by the health care industry, recognized by insurers, and valued by consumers as the best practice.

Codification of IPE into the health professional education accreditation standards is a first step,[14] but continuing education revolving around the IPEC core competencies is needed for all practicing professionals. As a move in this direction, the Joint Accreditation for Interprofessional Education™ has offered Interprofessional Continuing Education (IPCE) credits for learning and change that can be used by jointly accredited providers to identify activities that have been planned by and for the health care team.[35] Jointly accredited providers may choose to award single profession or IPCE credits to athletic trainers, dentists, dietitians, nurses, optometrists, PAs, pharmacists, physicians, psychologists, and social workers without needing to obtain separate accreditations.[36]

The landscape of interprofessional practice and education and the concept of collaborative care has moved from an experimental process into the mainstream. The appearance of multiple resources over the past decade that encourage, support, and guide this collaboration as well as promote the research to validate its importance is encouraging. The reader is advised to peruse the section Key Websites to access a wealth of further information.

Dyslipidemias, Atherosclerosis, and Coronary Heart Disease

Barbara S. Wiggins and Pamela Morris

CORE PRINCIPLES	CHAPTER CASES
1 The risk of atherosclerosis is directly related to increasing levels of serum cholesterol. Cholesterol, specifically lipoproteins, plays a central role in the pathogenesis of atherosclerosis. Thus, low-density lipoprotein cholesterol (LDL-C) is the primary target for intervention. The American College of Cardiology/American Heart Association (AHA/ACC) Multisociety guidelines recommend management for patients at high risk. This includes patients with atherosclerotic cardiovascular disease (ASCVD) as well as those with familial hypercholesterolemia (FH).	**Case 8-1 (Question 1)**

2	Every patient with dyslipidemia should be evaluated for secondary causes of elevated LDL-C, non–high-density lipoprotein cholesterol (non–HDL-C), or triglycerides (TGs). These causes may be related to concomitant medications or due to a clinical condition.	**Case 8-1 (Questions 2, 3), Table 8-5**
3	LDL-C and the thresholds for instituting therapeutic lifestyle changes (TLC) and pharmacotherapy are guided by the presence of clinical atherosclerosis or based on CV risk.	**Case 8-2 (Questions 1, 2)** **Case 8-3 (Question 1)** **Case 8-4 (Questions 1, 2)**
4	An adequate trial of TLC should be used in all patients, but pharmacotherapy should be instituted concurrently in high-risk patients and the patients should be monitored for adverse effects.	**Case 8-2 (Question 2)** **Case 8-5 (Question 1)**
5	Statins are considered first-line therapy to treat high LDL-C due to their ability to substantially lower LDL-C, ability to reduce morbidity and mortality from atherosclerotic disease, convenient once-daily dosing, and low risk of side effects. Management of these adverse effects is necessary in order to optimize benefit.	**Case 8-2 (Question 2)** **Case 8-3 (Questions 2, 3)**
6	Statins are the agents of choice to reduce LDL-C with low risk of adverse effects. However, drug interaction knowledge is needed in order to optimize efficacy without compromising safety.	**Case 8-4 (Question 3)**

7	Patients with high TGs are at increased risk of acute pancreatitis. The primary goal in these individuals is to lower their TG levels with diet, exercise, weight reduction, and TG-lowering drugs such as fibrates or ω-3 fatty acids.	**Case 8-5 (Question 2)** **Case 8-6 (Question 1)**
8	Combination drug therapy is often needed in patients with severe lipid abnormalities, higher risk individuals with lower LDL-C goals, or patients with multiple lipid abnormalities such as those with the metabolic syndrome who have a secondary target of non–HDL-C.	**Case 8-6 (Question 2)**

INTRODUCTION

Dyslipidemias (one or more abnormalities of blood lipids) play an important etiologic role in the pathogenesis of atherosclerotic cardiovascular disease (ASCVD), including coronary heart disease (CHD), cerebrovascular disease, and peripheral arterial disease (PAD).[1] Successful lifestyle changes and pharmacologic management of dyslipidemias have been shown to reduce the risk of ASCVD events, such as heart attack and stroke.[2–4] For cardiovascular disease (CVD) prevention, the clinician estimates the individual patient's ASCVD risk with available risk assessment tools, determines the intensity of lipid-modulating therapy to match the patient's level of risk, and implements appropriate treatments to meet and maintain treatment goals.[5]

LIPID METABOLISM

Knowledge of lipid and lipoprotein metabolism is essential to understanding therapeutic targets for pharmacologic agents. Lipids are small molecules that function in the body's storage of energy, in cellular signaling, and as components of cell membranes. Cholesterol, an essential lipid, is the precursor molecule for the formation of bile acids (which are required for absorption of nutrients), the synthesis of steroid hormones (which provide important modulating effects in the body), and the formation and integrity of cellular membranes. However, excess cholesterol plays a central role in atherogenesis and subsequent atherothrombotic complications.

Cells derive cholesterol in two ways: by intracellular synthesis or by uptake from the systemic circulation. Within each cell, cholesterol is synthesized through a series of biochemical steps, many of which are catalyzed by enzymes (**Fig. 8-1**). The irreversible and rate-limiting step in cholesterol production is the conversion of 3-hydroxy-3-methylglutaryl coenzyme A to mevalonic acid, which is catalyzed by HMG-CoA reductase. One of the most effective lipid-lowering therapies developed to date for managing dyslipidemias, HMG-CoA reductase inhibitors or statins, competitively interferes with the binding of substrate to this critical enzyme, thereby reducing the cellular synthesis of cholesterol. The biosynthesis of cholesterol in humans follows a circadian rhythm with maximum cholesterol synthesis occurring near midnight and minimum synthesis at midday.[5,6]

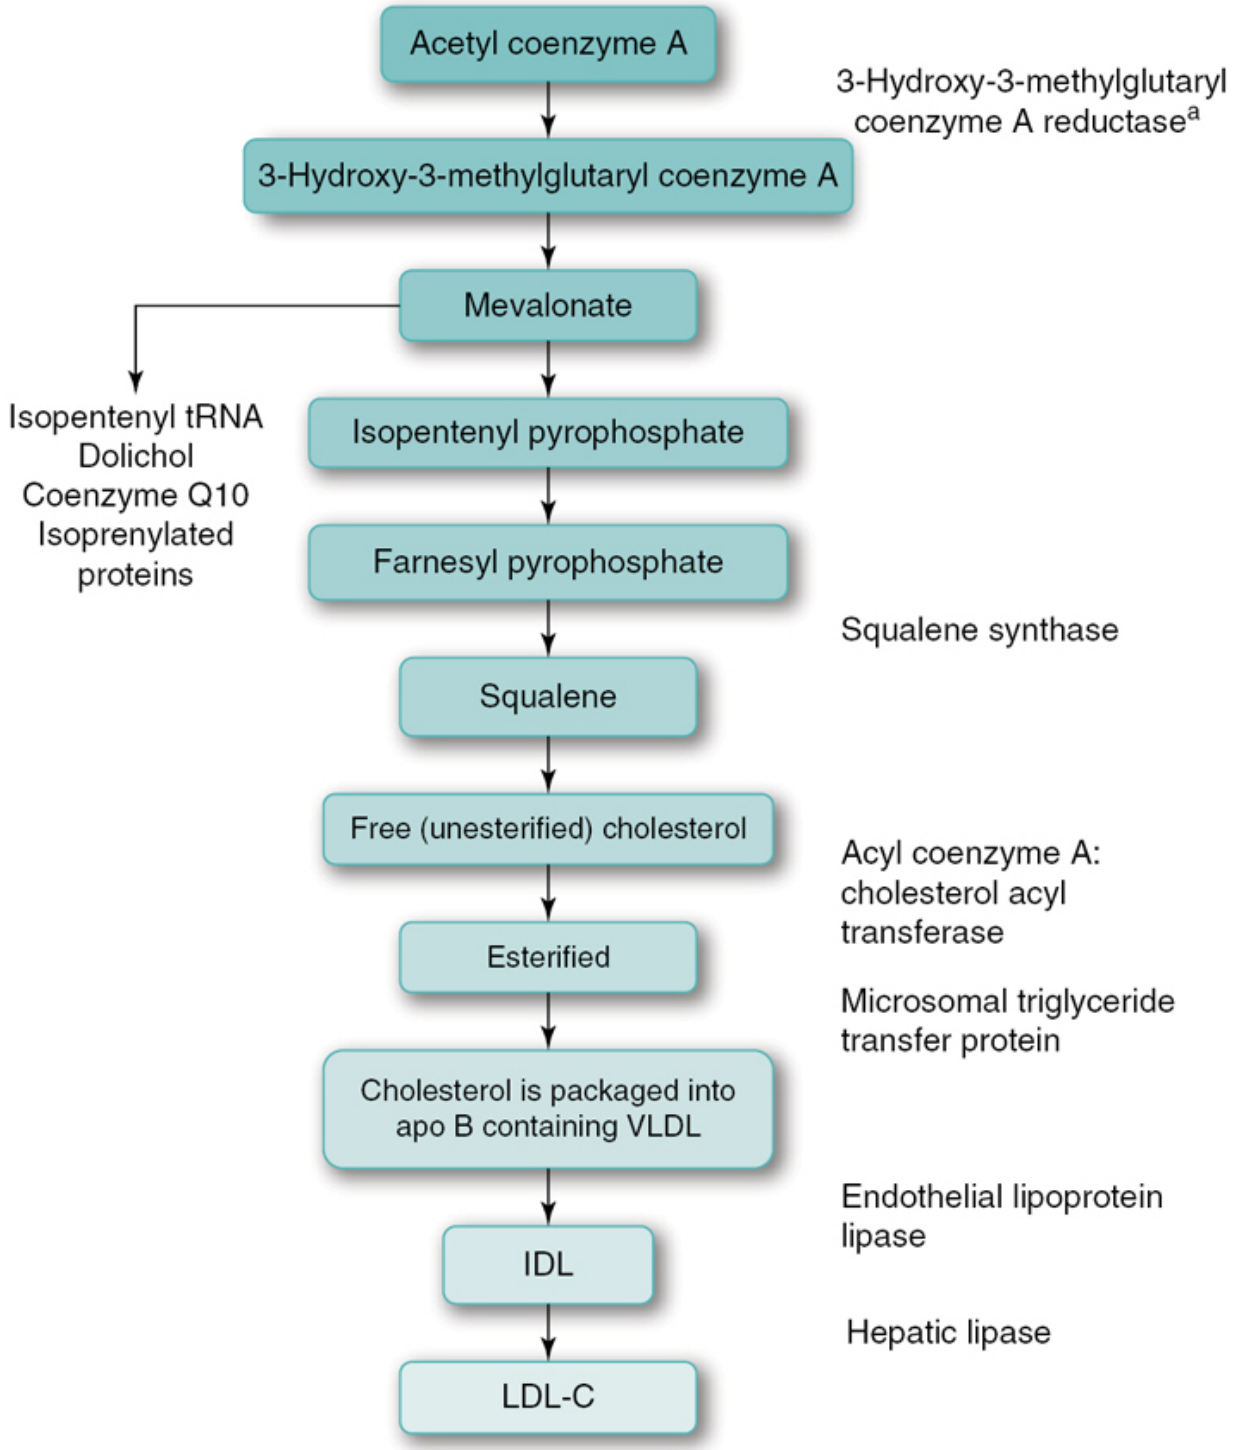

Figure 8-1 Biosynthetic pathway of cholesterol. apo B, apolipoprotein B; IDL, intermediate-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; VLDL, very low-density lipoprotein.[a]The rate-limiting step in cholesterol biosynthesis.

Free cholesterol is esterified to cholesteryl esters (CEs) for intracellular storage by the action of the enzyme acetyl-CoA acetyl transferase (ACAT). Two forms of ACAT have been identified. ACAT1 is present in many tissues, including inflammatory cells, whereas ACAT2 is present in intestinal mucosa cells and hepatocytes. ACAT2 is required for the esterification and absorption of dietary cholesterol from the gut. In theory, inhibition of this enzyme could reduce the absorption of dietary cholesterol, the secretion of cholesterol by the liver, and even the uptake and storage of circulating cholesterol in inflammatory cells in the arterial wall. Several inhibitors of ACAT have been developed; however, in clinical trials, they did not appear to reduce atherosclerosis and were possibly proatherogenic.[7] It is unlikely that there will be any further development of this class of drugs for CV prevention.

Triglycerides (TGs) are lipids that serve as an important source of stored energy in adipose tissue. TGs are synthesized from three molecules of fatty acids esterified to a glycerol backbone. Phospholipids (PLs) are a class of lipids formed from fatty acids, a negatively charged phosphate group, nitrogen-containing alcohol, and a glycerol backbone. PLs are essential for cellular function and the absorption, storage, and transport of lipids in the circulation. They form the monolayer on the surface of lipoproteins, which function to transport neutral lipids throughout the body. PLs are amphipathic with a hydrophilic head and hydrophobic tail and form a membrane bilayer of lipoproteins to deliver hydrophobic cargo (cholesterol and energy in the form of fat) to other organs. PLs are also secreted into bile to aid in the digestion and absorption of dietary fat and lipid-soluble nutrients from the diet. They stabilize proteins within the membrane, function as cofactors in enzymatic reactions, and participate in the oxidation of lipoproteins in the arterial wall (**Fig. 8-2**).

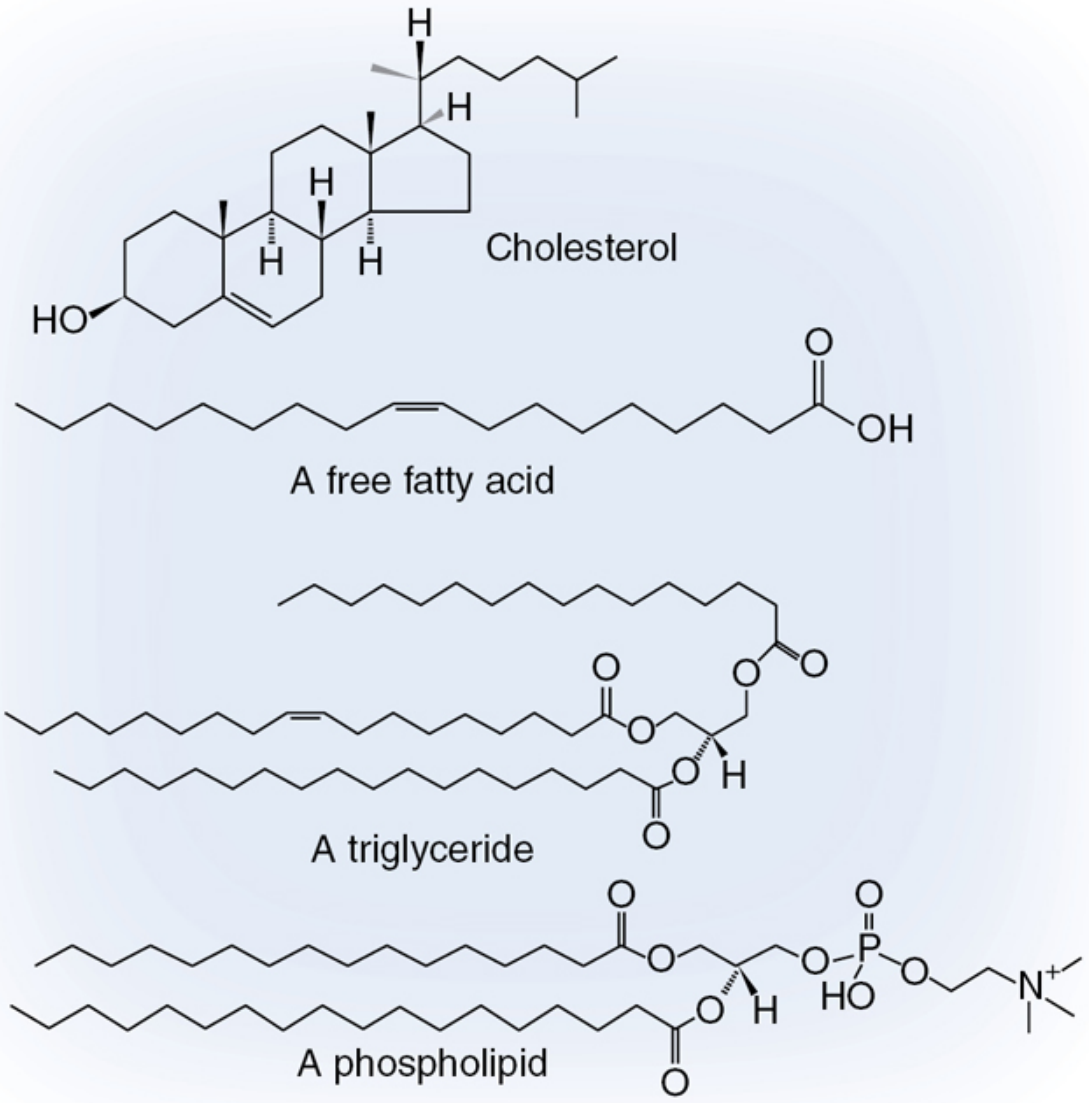

Figure 8-2 Chemical structure of lipids. At the top is cholesterol, followed by oleic acid. In the middle is a triglyceride composed of an oleoyl, stearoyl, and palmitoyl chain attached to a glycerin backbone. At the bottom is a phospholipid.

Lipoproteins

Cells also obtain cholesterol by extracting it from the systemic circulation. The source of this cholesterol is the liver, where it is synthesized and secreted into the systemic circulation. As discussed

earlier, cholesterol and other fatty substances are insoluble in water. Therefore, cholesterol, TGs, and PLs are packaged into water-soluble complexes called lipoproteins in the hepatocyte and enterocytes before being secreted into the aqueous medium of the blood. These lipoproteins contain an oily inner lipid core made up of CEs and TGs and an outer hydrophilic coat made up of PLs and unesterified cholesterol (**Fig. 8-3**). The outer coat also contains at least one of a number of proteins known as "apoproteins," which provide the ligand for interaction with receptors on cell surfaces, act as cofactors for various enzymes, and add structural integrity.

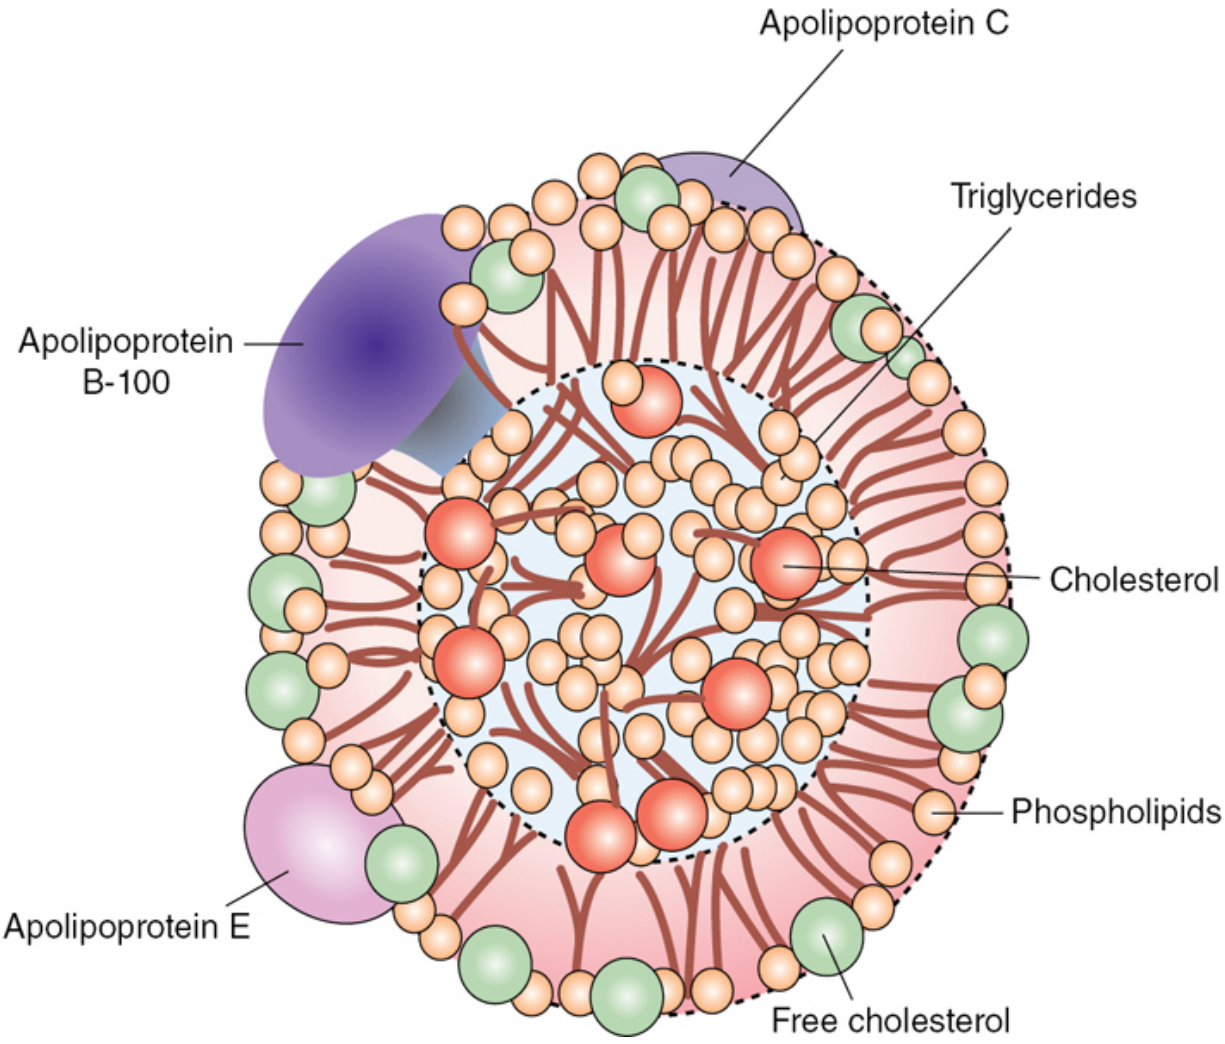

Figure 8-3 Basic structure of lipoproteins. Lipoproteins vary in the amount of cholesterol esters and triglyceride content. In addition, they have varying numbers and types of surface apolipoproteins.

The three major lipoproteins found in the blood of fasting (10–12 hours) patients are very low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL).[8] These particles vary in size, cholesterol and TG composition, and accompanying proteins (**Table 8-1** and **Fig. 8-4**).[9,10]

Table 8-1
Classification and Properties of Plasma Lipoproteins

Lipoprotein	Origin	Density Range (g/mL)	Size (nm)	Cholesterol Concentration in Plasma (mmol/L)[a]	Triglyceride Concentration in Plasma (mmol/L)[b]	Major Apolipoprotein	Other Apolipoprotein
Chylomicrons	Intestine	<0.95	100–1000	0.0	0	B-48	A-I, C
VLDL	Liver	<1.006	40–50	0.1–0.4	0.2–1.2	B-100	A-I, C
IDL	VLDL	1.006–1.019	25–30	0.1–0.3	0.1–0.3	B-100	
LDL	IDL	1.019–1.063	20–25	1.5–3.5	0.2–0.4	B-100	
HDL	Tissues	1.063–1.21	6–10	0.9–1.6	0.1–0.2	A-I	A-II, A-IV

VERY LOW-DENSITY LIPOPROTEINS

VLDL particles are formed in the liver. Free fatty acids are taken up by the hepatocyte where the enzyme diglycerol acyltransferase (DGAT) catalyzes TG formation from diacylglycerol and the

coenzyme acyl-CoA. The enzyme microsomal triglyceride transfer protein (MTP) lipidates apoprotein B by transfer of CEs and TG to form VLDL, which is then secreted by the liver into the circulation. Inhibitors of MTP reduce production of VLDL and downstream intermediate-density lipoprotein (IDL) and LDL. One of these agents, lomitapide, is currently approved for the treatment of the homozygous form of familial hypercholesterolemia (FH).[11] DGAT inhibitors that reduce TG synthesis are currently under investigation for the management of obesity and hypertriglyceridemia.[12]

VLDL particles normally contain 15% to 20% of the total blood cholesterol concentration and most of the total blood TG concentration. The concentration of cholesterol in these particles is approximately one-fifth of the total TG concentration; thus, if the total TG concentration is known, the VLDL cholesterol (VLDL-C) level can be estimated by dividing total TGs by 5. Newly secreted VLDL particles are too large to migrate into the arterial wall and appear to play only a small role in the pathogenesis of atherosclerosis.

VERY LOW-DENSITY LIPOPROTEIN REMNANTS

In the circulation, the enzyme lipoprotein lipase (LPL) hydrolyzes TGs in VLDL particles. The removed TGs are converted to fatty acids and stored as an energy source in adipose tissue. As TGs are removed, the VLDL particle becomes progressively smaller and relatively more cholesterol rich. The particles formed through this process include small VLDL particles (called remnant VLDL), IDL, and LDL (**Fig. 8-5**). Approximately 50% of the remnant VLDL and IDL particles are removed from the systemic circulation by LDL or apolipoprotein (apo) B-100/apo E receptors on the surface of the liver; the other 50% are converted into LDL particles by further hydrolytic action of hepatic lipase. VLDL remnant particles are found in the arterial wall, though in smaller numbers than LDL. Drugs that enhance the activity of LPL, such as the fibrates, increase hydrolysis of TG in VLDL particles and lower blood TG levels.

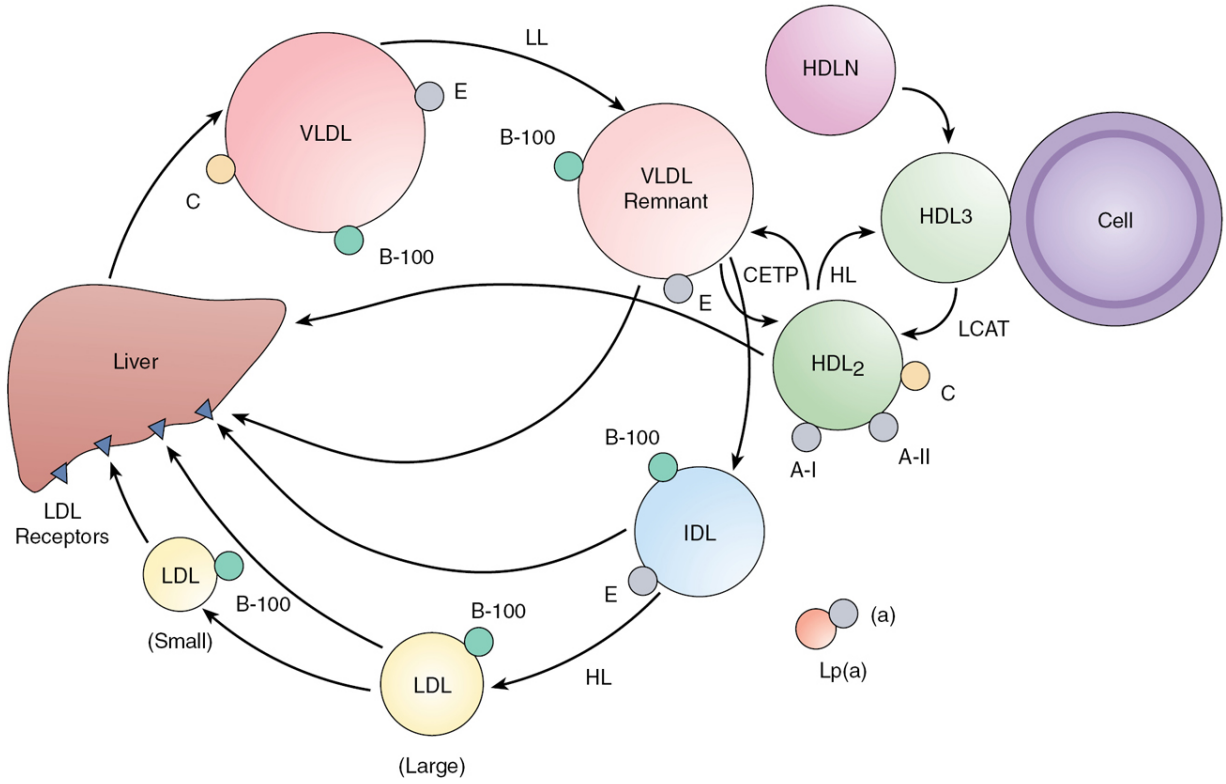

Figure 8-5 The lipoproteins, apolipoproteins, and enzymes involved in the transport of cholesterol and triglycerides. LOW-DENSITY LIPOPROTEINS

LDL particles are cholesterol enriched and carry 60% to 70% of the total blood cholesterol. LDL plays a central role in the pathogenesis of atherosclerosis and is the primary target of lipid-lowering therapy. Approximately half of the LDL particles are removed from the systemic circulation by the liver; the other half may be taken up by peripheral cells or deposited in the intimal space of coronary, carotid, and other peripheral arteries, where atherosclerosis can develop. The probability that atherosclerosis will develop is directly related to

the concentration of LDL-C in the systemic circulation and the duration of exposure to elevated LDL-C levels; thus, the cumulative risk of ASCVD in males and females with hypercholesterolemia increases with age.

HIGH-DENSITY LIPOPROTEINS

HDL particles transport cholesterol from peripheral, lipid-rich inflammatory cells in the arterial wall back to the liver, a process called *reverse cholesterol transport.*[13] In epidemiologic studies, HDL cholesterol (HDL-C) concentrations are inversely associated with the risk of ASCVD, presumably because cholesterol is being removed from vascular tissue and is not available to contribute to atherogenesis. In peripheral cells, the adenosine triphosphate binding cassette transporter A-1 (ABCA-1) and adenosine triphosphate binding cassette transporter G-1 facilitate the efflux of both cholesterol and PLs to apo A1 to form nascent HDL particles. Cholesterol acquired from peripheral cells by HDL particles is converted into an esterified form through the action of the enzyme lecithin cholesterol acyltransferase (LCAT). HDL particles may either transport cholesterol directly to the liver through interaction with the scavenger receptor, SR-B1, on the surface of hepatocytes or transfer it to circulating remnant VLDL and LDL particles by the action of cholesteryl ester transfer protein (CETP). CETP transfers cholesterol from HDL particles to VLDL and LDL in exchange for TGs, making the HDL particle less cholesterol rich. If the latter occurs, cholesterol may be returned to the liver for clearance from the circulation or delivered back to peripheral cells. Patients have been identified who have a deficiency of CETP and high plasma concentration of HDL-C, which appears to be associated with a low incidence of CHD. Drugs that inhibit CETP can raise HDL-C levels and are being studied in long-term CV outcomes trial.[14]

NON–HIGH-DENSITY LIPOPROTEIN CHOLESTEROL

Though elevated LDL-C is most commonly associated with ASCVD risk, in some patients, the assessment of LDL-C alone may

underestimate the risk of events. Non–HDL-C, calculated by subtracting HDL-C from total cholesterol (TC), provides a measure of cholesterol carried by all potentially atherogenic particles, including VLDL, VLDL remnants, IDL, and LDL particles. Also, in the presence of postprandial hypertriglyceridemia, the calculation of LDL-C may be inaccurate, whereas non–HDL-C is reliable when measured in the nonfasting state.

CHYLOMICRONS

Unlike the lipoproteins that transport cholesterol from the liver to peripheral cells and back (endogenous lipid transport), chylomicrons transport TGs and cholesterol derived from the diet or synthesized in the enterocytes from the gut to the liver (exogenous lipid transport) (see **Fig. 8-5** and Table 8-1). Chylomicrons are large, TG-rich lipoproteins. As they pass through capillary beds on the way to the liver, some of the TG content is removed through the action of LPL in a manner similar to that described for hydrolysis of TGs from VLDL particles. In the rare individual who has LPL deficiency, chylomicrons are inefficiently metabolized and TG levels in the blood may become severely elevated (eg, 1000–5000 mg/dL).

After a fatty meal, the number of TG-rich chylomicron particles is elevated and TG levels rise. Following a 10- to 12-hour period of fasting, chylomicrons will be removed from the blood by LPL-mediated hydrolysis of TGs and removal of chylomicron remnants in the liver. TG concentrations measured in the fasting state reflect primarily TGs that are produced by the liver as well as TGs carried in VLDL and other remnant particles. For this reason, most patients are asked to fast before a lipoprotein profile is obtained. A blood sample that is rich in chylomicrons (and to a lesser extent VLDL particles) appears turbid; the higher the TG level, the more turbid the sample. If the sample from a patient with hyperchylomicronemia is refrigerated, chylomicrons will float to the top and form a frothy white layer, whereas smaller VLDL particles stay suspended below.

Apolipoproteins

Each lipoprotein particle contains proteins on the outer surface called *apolipoproteins* (see **Fig. 8-5** and Table 8-1). These proteins serve four main functions: (a) they serve as major structural components of lipoproteins, (b) they serve as cofactors for activation of enzyme systems, (c) they act as ligands for binding to receptors on cell surfaces, and (d) they are required for assembly and secretion of lipoproteins.[12] Abnormal metabolism of apolipoproteins can result in faulty enzyme activity or cholesterol transport and an increased risk of atherosclerosis. Clinicians may consider assessment of blood levels of apolipoproteins to evaluate dyslipidemic patients, especially those who have a family history of premature CHD. The five most clinically relevant apolipoproteins are B-100, C, E, A-I, and A-II.

VLDL particles contain apo B-100, apo E, and apo C (see **Fig. 8-5**). The B and E proteins are ligands for LDL receptors (also called *B-E receptors*) on the surface of hepatocytes and peripheral cells. Linkage allows the transfer of cholesterol from the circulating lipoprotein into the cell through absorptive endocytosis and cellular uptake of the particle. Defects in these proteins reduce the ability of lipoproteins to bind with receptor proteins and may result in defective clearance of lipoproteins from the systemic circulation and increased levels of circulating cholesterol.

Apo C-II is a cofactor or activator of LPL. By activating LPL, apo C-II stimulates the hydrolysis of TGs from lipoprotein particles in the capillary beds. Deficiency of apo C-II may result in faulty TG metabolism and subsequent hypertriglyceridemia. Apo C-III downregulates LPL activity and interferes with the hepatic uptake of VLDL remnant particles. This leads to increased concentrations of small VLDL remnant particles, which are small enough to penetrate into the arterial wall and contribute to atherogenesis. Apo C-III is a marker of atherogenic dyslipidemia (elevated TGs, reduced HDL-C, near-normal levels of LDL-C, and elevated LDL particle concentration), which is associated with an increased risk of ASCVD events. In addition, prolonged residence of VLDL and LDL particles in the systemic circulation results in the formation of small, highly

atherogenic LDL particles and the atherogenic dyslipidemia (see later).[15]

Each VLDL, IDL, and LDL particle contains one molecule of apo B-100. Thus, the blood concentration of apo B-100 is an indication of the total number of VLDL, VLDL remnant, IDL, and LDL particles in the circulation. An increased number of lipoprotein particles and an increased apo B-100 concentration are strong predictors of ASCVD risk.[16] Remnant VLDL particles retain both apo B-100 and apo E during the delipidization process; LDL particles contain only apo B-100 (see **Fig. 8-5**). Some patients have high levels of apo B-100, suggesting an increased number of atherogenic particles in the circulation, even though the LDL-C level is in the desirable range. These patients have an increased risk of atherosclerosis. Apo B-100 and the measurement of LDL particle concentrations by nuclear magnetic resonance spectroscopy are considered recommended treatment targets by some guidelines for the management of dyslipidemia.[17,18]

HDL particles contain apo A-I, apo A-II, and apo C. Apo A-I is an activator of LCAT, which catalyzes the esterification of free cholesterol in HDL particles. Levels of apo A-I have a stronger inverse correlation with CHD risk than apo A-II levels. HDL particles that contain only A-I apolipoproteins are associated with a lower CHD risk than are HDL particles containing both A-I and A-II.[19]

Low-Density Lipoprotein Receptor

Cholesterol is taken up by peripheral and hepatic cells via binding of the ligands, apo B-100, and apo E, on circulating lipoproteins to cell-surface LDL receptors. The concentration of LDL receptors is mediated by intracellular cholesterol concentration. Synthesis of LDL receptors is stimulated by a low intracellular cholesterol concentration. Conversely, the concentration of cell-surface LDL receptors may be downregulated by the action of proprotein convertase subtilisin/kexin type 9 (PCSK9), which targets the LDL receptor for degradation within intracellular lysozymes.[20] Within the

cell, the receptor protein is synthesized in the mitochondria and migrates to clathrin-coated pits on the cell surface. The LDL receptor may then bind to lipoproteins that contain apo E or apo B-100, including VLDL, remnant VLDL, IDL, and LDL. Because remnant VLDL and IDL particles contain both B-100 and E proteins, they may have a higher affinity for LDL receptors than do LDL particles, which contain only the B protein. Drugs that upregulate the synthesis of LDL receptors (eg, statins), therefore, may increase the clearance of both VLDL remnant particles and LDL particles from the circulation. Thus, statins may reduce serum TG levels as well as cholesterol levels. Following binding of lipoproteins to the LDL receptor, the lipoproteins undergo endocytosis and are taken up by lysosomes, where they are metabolized into elemental substances for use by the cell. The cholesterol is transferred into the intracellular cholesterol pool. The LDL receptor may be returned to the cell surface, where it can bind with another circulating apo E– or apo B–containing lipoprotein.

ABNORMALITIES IN LIPID METABOLISM

Lipid synthesis and transport is complex with hundreds of possible steps that can malfunction resulting in a lipid disorder. However, there are only a few relatively common and important lipid disorders seen in clinical practice. The first two described subsequently, polygenic hypercholesterolemia and atherogenic dyslipidemia, are largely the result of an interaction between genes and lifestyle choices. Several prominent, but rarer, familial lipid disorders are subsequently described. **Table 8-2** summarizes the characteristics of the most common lipid disorders.

Table 8-2
Characteristics of Common Lipid Disorders

Disorder	Metabolic Defect	Lipid Effect	Main Lipid Parameter	Diagnostic Features
Polygenic hypercholesterolemia	↓LDL clearance	↑LDL-C	LDL-C: 130–250 mg/dL	None distinctive
Atherogenic dyslipidemia	↑VLDL secretion ↑Apo C-III synthesis ↓LPL activity ↓VLDL removal	↑TG ↑Remnant VLDL ↓HDL ↑Small, dense LDL	TG: 150–500 mg/dL HDL-C: <40 mg/dL	Frequently accompanied by central obesity or diabetes
Familial hypercholesterolemia heterozygous	Reduction in functional LDL receptor, defective apo B, gain-of-function mutations PCSK9	↑LDL-C	LDL-C: 250–450 mg/dL	Family history of premature CHD, tendon xanthomas, corneal arcus
Familial hypercholesterolemia homozygous	Absent LDL receptors, defective apo B, gain-of-function mutations PCSK9	↑LDL-C	LDL-C: >450 mg/dL	Family history of premature CHD, tendon xanthomas, corneal arcus; affected individuals exhibit CHD by the second decade of life
Familial defective apo B-100	Defective apo B on LDL and VLDL	↑LDL-C	LDL-C: 250–450 mg/dL	Family history of CHD, tendon xanthomas
Dysbetalipoproteinemia (type III hyperlipidemia)	Apo E2:E2 phenotype, ↓VLDL remnant clearance	↑Remnant VLDL, ↑IDL	LDL-C: 300–600 mg/dL TGs: 400–800 mg/dL	Palmar xanthomas, tuberoeruptive xanthomas
Familial combined hyperlipidemia	↑Apo B and VLDL production	↑CH, TG, or both	LDL-C: 250–350 mg/dL TGs: 200–800 mg/dL	Family history, CHD Family history, hyperlipidemia
Familial hyperapobetalipoproteinemia	↑Apo B production	↑Apo B	Apo B: >125 mg/dL	None distinctive
Hypoalphalipoproteinemia	↑HDL catabolism	↓HDL-C	HDL-C: <40 mg/dL	None distinctive

Apo B, apolipoprotein B; apo C-III, apolipoprotein C-III; apo E, apolipoprotein E; CH, cholesterol; CHD, coronary heart disease; HDL, high-density lipoprotein; HDL-C, high-density lipoprotein cholesterol; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; TGs, triglycerides; VLDL, very low-density lipoprotein.

Polygenic Hypercholesterolemia

Polygenic hypercholesterolemia is the most prevalent primary disorder causing an increase in cholesterol. It is caused by a combination of environmental (eg, poor nutrition, sedentary lifestyle) and multiple genetic factors. In patients with this disorder, a diet high in saturated fatty acids can reduce LDL receptor activity, thus reducing the clearance of LDL particles from the systemic circulation. Patients with polygenic hypercholesterolemia have mild-to-moderate LDL-C elevations (usually in the range of 130–250 mg/dL), but no unique physical findings are usually present. A family history of premature CHD is present in ~20% of cases. These patients may often be effectively managed with dietary restriction of saturated fats and cholesterol and by drugs that lower LDL-C levels (statins, bile acid sequestrants [BASs], and ezetimibe).

Atherogenic Dyslipidemia

Atherogenic dyslipidemia is characterized by moderate elevations of TG (150–500 mg/dL, indicative of the elevated VLDL remnant particles), low HDL-C levels (<40 mg/dL), and mild-to-moderate elevations of LDL-C level.[21] These patients have increased concentrations of small, dense, cholesterol-poor LDL particles, non–HDL-C, and apo B-100. Most commonly, patients have increased visceral adiposity and are hypertensive and insulin resistant.

In the presence of increased visceral adiposity, there is impaired glucose metabolism and/or diabetes with increased mobilization of fatty acids from adipose cells to the systemic circulation. The excess of free fatty acids leads to increased TG synthesis and secretion of TG-rich VLDL particles by the liver. These TG-rich particles contain apo C-III, which inhibits the action of LPL, thus retarding lipolysis of TGs from VLDL particles. This results in an excess of TG-rich VLDL remnant particles.[22] CETP mediates the exchange of TGs from these particles with CEs from HDL, resulting in VLDL remnant particles that are enriched with cholesterol (**Fig. 8-6**). TGs are also exchanged from VLDL remnant particles with CEs from LDL particles. Thus, VLDL remnants become even more cholesterol enriched and LDL particles become TG enriched. The cholesterol-enriched, small VLDL remnant particle is atherogenic. TG-rich LDL undergoes lipolysis catalyzed by hepatic lipase to remove TGs, resulting in small, cholesterol-poor LDL particles (called *small dense LDL*) that are highly atherogenic. Lipolysis of TG-rich HDL results in low HDL because of excretion of lipid-poor apo A-I by the kidneys.

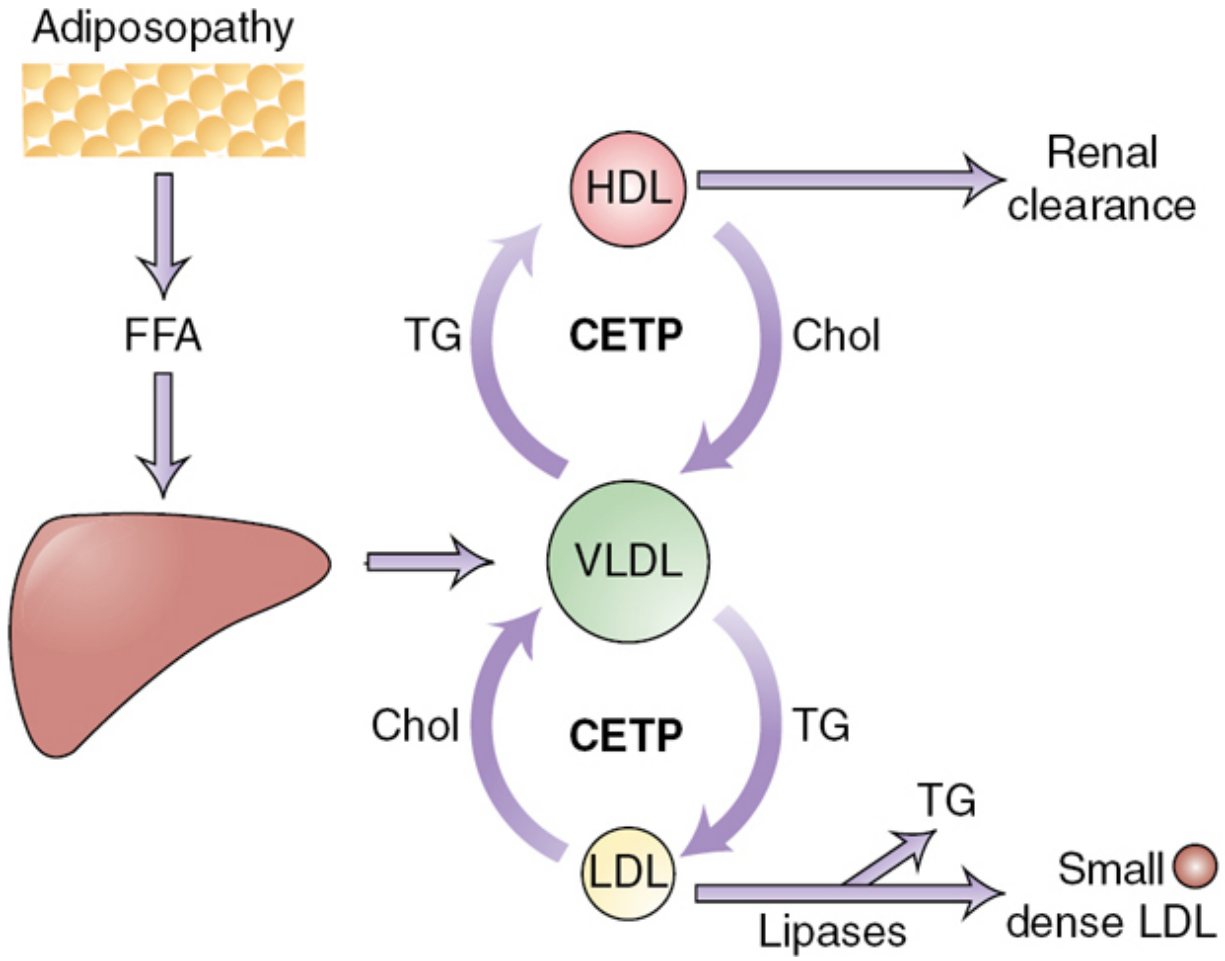

Figure 8-6 The role of CETP in creation of atherogenic dyslipidemia. Role of CETP in the creation of an atherogenic lipid of someone with hypertriglyceridemia. Cholesterol-rich VLDL, low HDL-C, as well as small dense LDL-C is a pattern often observed in patients with metabolic syndrome as well as those with type 2 diabetes. CETP, cholesteryl ester transfer protein; FFA, fenofibric acid; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; TG, triglycerides; VLDL, very low-density lipoprotein. (From Bays H, Stein EA. Pharmacotherapy for dyslipidaemia—current therapies and future agents. *Expert Opin Pharmacother*. 2003;4(11):1901–1938. Reprinted by permission of Taylor & Francis Ltd, http://www.tandfonline.com)

Patients with atherogenic dyslipidemia may be effectively managed with weight reduction and increased physical activity. Pharmacologic agents that enhance the removal of remnant VLDL

and small dense LDL particles (ie, statins) and that lower TG levels (ie, ω-3 fatty acids or fibrates) may be effective in the management of these patients.

Familial Hypercholesterolemia

FH is a disorder of defective LDL-C clearance. This autosomal dominant disorder is strongly associated with premature CHD.[23,24] Most recent estimates indicate that the prevalence of heterozygous FH (HeFH) ranges from 1 of 250 to 1 of 500 people in the United States.[25] Homozygous FH (HoFH) may occur in 1 of 1 million to 1 of 250,000 people in the United States. The most common cause of this disorder is a genetic mutation, resulting in a defective or absent LDL receptor. Consequently, heterozygotes possess approximately half the number of functioning LDL receptors and double the LDL-C level of unaffected patients (LDL-C levels ranging between 250 and 450 mg/dL). Clinically, patients with FH may exhibit excess cholesterol deposition in the iris, clinically manifested as arcus senilis. Cholesterol may also deposit in tendons, particularly the Achilles' tendon and extensor tendons of the hands, resulting in tendon xanthomas. The clinical diagnosis of FH is established by documenting a very high LDL-C level, a strong family history of hypercholesterolemia and premature CHD events, and the presence of tendon xanthomas. Untreated HeFH patients have approximately a 5% chance of a myocardial infarction (MI) by age 30 years, a 50% chance by age 50 years, and an 85% chance by age 60 years. The mean age of death in untreated male heterozygotes is in the mid-50s; for untreated female heterozygotes, it is in the mid-60s.[24]

Homozygotes generally have LDL-C levels >500 mg/dL. This rare disorder results in CHD by ages 10 to 20 years. Because these individuals have lost the ability to clear cholesterol-carrying lipoproteins from the circulation, combination pharmacotherapy and/or LDL apheresis may be required to help remove atherogenic particles.

Familial Defective Apo B-100

Familial defective apo B-100 (FDB) is a genetic disorder clinically indistinguishable from HeFH. These patients have normally functioning LDL receptors, but defective apo B-100, resulting in reduced binding of LDL particles to the LDL receptor and reduced clearance of LDL particles from the systemic circulation.[26–28] As with FH, LDL-C levels are usually 250 to 450 mg/dL. Presumably, the apo E and half of the apo B in heterozygous FDB patients function normally, providing mechanisms for removal of some lipoproteins from the systemic circulation. Clinical diagnosis of FDB is based on a very high LDL-C level, a family history of premature CHD, and tendon xanthomas. The definitive diagnosis requires molecular screening techniques.

Proprotein Convertase Subtilisin/Kexin Type 9 Gain-of-Function Gene Mutation

FH may also be caused by “gain-of-function” mutations in the gene encoding for PCSK9, an enzyme that plays an important role in cholesterol homeostasis.[29] The frequency of these mutations in patients with FH is uncertain. When PCSK9 is secreted into the plasma, it binds to the epidermal growth factor–like repeat A (EGF-A) domain of the cell-surface LDL receptors. PCSK9 binding leads to endocytosis of the LDL–LDL receptor–PCSK9 complex into intracellular lysozymes for degradation, resulting in a reduced number of LDL receptors and increased LDL-C (~300 mg/dL). Drugs that inhibit PCSK9 have demonstrated significant reductions in LDL-C in patients with HeFH, HoFH, and polygenic hypercholesterolemia.[30]

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) is caused by increased production of apo B–containing particles, VLDL, and LDL.[31] Patients

with FCHL have an elevated apo B-100 level, hypercholesterolemia with LDL-C usually in the range of 250 to 350 mg/dL, elevated TGs (usually between 200 and 800 mg/dL), and reduced levels of HDL-C. First-degree relatives of these individuals frequently have a lipid disorder, and there is often a family history of ASCVD. Patients with FCHL commonly are overweight, are hypertensive, and may have metabolic disturbances, such as insulin resistance, diabetes, or hyperuricemia. The diagnosis of FCHL is presumed in patients who have increased cholesterol or TG levels, a strong family history of premature CHD, and a family history of dyslipidemia.

Familial Dysbetalipoproteinemia

Familial dysbetalipoproteinemia, also called type III hyperlipidemia or remnant disease, is caused by poor clearance of VLDL and chylomicron particles from the systemic circulation as a result of a defect in apo E.[32,33] Apo E is necessary for the normal clearance of chylomicrons and VLDL. It is inherited as an E2, E3, or E4 isoform from each parent. The E2 isoform has a low binding affinity for the LDL receptor. Thus, individuals with an apo E2/E2 phenotype have delayed clearance of VLDL remnant (and possibly chylomicron) particles from the circulation and a reduced conversion of IDL to LDL particles. However, a clinically significant lipid disorder usually does not result unless triggered by other metabolic problems, such as diabetes, hypothyroidism, or obesity. Patients with this disorder have high cholesterol due to enrichment of cholesterol esters in VLDL remnant particles, high TGs in the range of 400 to 800 mg/dL, and a VLDL-C to TG ratio >0.3. Patients may have palmar xanthomas (yellow-orange discoloration in the creases of the palms and fingers) and tuberoeruptive xanthomas (small, raised lesions in areas of pressure, particularly the elbows and knees). A personal and family history of premature atherosclerotic vascular disease is often present. As noted earlier, these patients often have diabetes mellitus, hypertension, obesity, and hyperuricemia.

Familial Disorders of Triglyceride Metabolism

Familial hypertriglyceridemia (FHTG) is associated with an increase in both TG-rich VLDL particles and chylomicrons. LDL-C is generally not significantly elevated (<130 mg/dL), and HDL-C is decreased (<40 mg/dL). FHTG is usually relatively mild and asymptomatic unless secondary causes of hypertriglyceridemia are present (poorly controlled diabetes, obesity, medications, etc.). TG levels are in the range of 200 to 500 mg/dL, but may be >1000 mg/dL. Patients with more marked TG elevations (>500 mg/dL) may present with eruptive xanthomas and/or acute pancreatitis.

Rare mutations in the *LPL* or cofactor *apo CII* genes may also be associated with severe hypertriglyceridemia.[34] Familial LPL deficiency usually presents in childhood with TG levels from 2000 to 25,000 mg/dL and lipemic plasma, pancreatitis, eruptive xanthomas, and lipemia retinalis (creamy white appearance of retinal blood vessels). The clinical presentation of familial deficiency in apo CII is similar to familial LPL deficiency in homozygotes, but heterozygous individuals may have normal plasma lipid concentrations. Patients with familial hepatic lipase deficiency may also present with severe hypertriglyceridemia (>500–1000 mg/dL) associated with modest elevations in LDL-C and normal to increased HDL-C. This disorder is most common in individuals of Indian ancestry.

Hypoalphalipoproteinemia

Isolated low HDL-C (<40 mg/dL) without an increase in TG level is fairly uncommon, but is associated with increased ASCVD risk. The precise molecular defects causing this problem are uncertain, although genetic influences are likely involved.[35] Tangier disease, which is characterized by low HDL-C, orange tonsils, and hepatosplenomegaly, has been linked to a defect in the ABCA-1 transporter responsible for the efflux of cholesterol from peripheral cells (ie, inflammatory cells in the arterial wall). The inherited tendency to have low HDL-C is accentuated by lifestyle factors, such as obesity, smoking, and lack of exercise. Despite strong

epidemiologic evidence showing an inverse relationship between HDL-C and CHD, clinical trials demonstrating a benefit of raising isolated low HDL-C with drugs are lacking. Therapy in patients with low HDL-C is, therefore, directed at lowering LDL-C to reduce ASCVD risk. Therapies to raise HDL-C by novel mechanisms are under investigation to determine whether HDL-directed strategies can reduce CHD risk.[36]

LIPOPROTEINS AND ATHEROSCLEROTIC CARDIOVASCULAR DISEASE RISK

Epidemiologic studies have conclusively established a direct relationship between blood cholesterol concentrations in a population and the incidence of ASCVD events.[37–39] For every 1% increase in blood cholesterol levels, there is a 1% to 2% increase in the risk of CHD. In addition, using gene variants that exclusively affect a biomarker of interest (ie, that do not have pleiotropic effects on other factors), investigators have confirmed LDL-C as a causal risk factor for coronary artery disease (CAD). HDL-C is inversely associated with CHD risk. For every 1% *decrease* in HDL-C levels, there is a 1% to 2% *increase* in the risk of CHD events.[40] However, gene variants that affect HDL-C have cast doubt on whether HDL-C directly influences risk for CAD.

The role of TGs in the pathogenesis of ASCVD continues to be a subject of important investigation.[22] Most epidemiologic studies have found that a high TG level is an independent risk factor for CHD when evaluated with univariate analysis. When other lipid abnormalities such as increased LDL-C or low HDL-C are included in a multivariate analysis, TGs may lose independent predictive power. This is, in part, because it is difficult to establish a causal relationship in observational epidemiology, especially given the correlations among TGs, LDL-C, and HDL-C. Patients with hypertriglyceridemia usually have low HDL-C (due to the action of CETP and increased

renal clearance of apo AI), which is an important predictor of ASCVD risk. In addition, elevated TG levels are associated with increased levels of TG-rich lipoprotein remnants (remnant VLDL and chylomicron particles and IDL), increased LDL particle concentration, and small, dense LDL particles. These particles are all potentially atherogenic and mediate a higher CHD risk than that associated with an elevated LDL-C alone.[41–44] Recent meta-analyses of epidemiologic studies found that TGs independently predicted CHD risk, even after adjustment for other lipid risk factors.[22] High TG levels are also found in certain familial disorders, including dysbetalipoproteinemia and FCHL, which carry increased CHD risk.[32,33] In addition, hypertriglyceridemia is associated with a procoagulant state, which promotes coronary thrombosis.[44]

A recent analysis of 185 common genetic variants mapped for plasma lipids examined the role of TGs in risk for CAD. In a model accounting for effects on LDL-C and/or HDL-C levels, the strength of a polymorphism's effect on TG levels was correlated with the magnitude of its effect on CAD risk.[45] These results suggest that TG-rich lipoproteins causally influence risk for CAD.

Paradoxically, very high TG levels (>500 mg/dL) are not commonly associated with an increased CHD risk but do cause an increased risk of pancreatitis, especially when levels exceed 1000 mg/dL. Often, a genetic defect in LPL is present in these cases that impair the removal of TGs from TG-rich particles (VLDL and chylomicrons). These particles do not become enriched with cholesterol and, therefore, are not often atherogenic.[46] If the blood sample is stored in the refrigerator overnight, a thick creamy layer often appears on the surface, indicating the presence of chylomicrons. Although most patients with very high TGs remain free of CHD throughout their lives, some do experience ASCVD events.

Pathogenesis of Atherosclerosis

Circulating cholesterol plays a central etiologic role in the pathogenesis of atherosclerosis.[1] Atherosclerotic vascular lesions

begin in the first decade of life and may progress in the presence of elevated levels of cholesterol and other uncontrolled ASCVD risk factors.[47] Atherosclerosis is considered to be a chronic inflammatory process in response to injury of the vascular endothelium by factors such as glycoxidation products in diabetes, shear stress, excess free fatty acids released by adipocytes, bacterial products, and neurohormonal abnormalities, among other factors. The damaged endothelium becomes prothrombotic, has reduced release of nitric oxide and impaired vasodilatory capacity, and releases chemoattractants for inflammatory cells and platelets. Regulation of blood cholesterol levels and management of other risk factors can restore endothelial function, nitric oxide release, and the vasodilatory response.

In patients with excess apo B–containing lipoproteins (VLDL remnants, IDL, LDL, and Lp[a]), atherogenic particles migrate through the endothelial junction into the subendothelial space or intima. The subsequent accumulation and retention of lipoproteins in the subendothelium (**Fig. 8-7**)[47] is the result of binding to subendothelial matrix molecules, such as chondroitin sulfate proteoglycans.

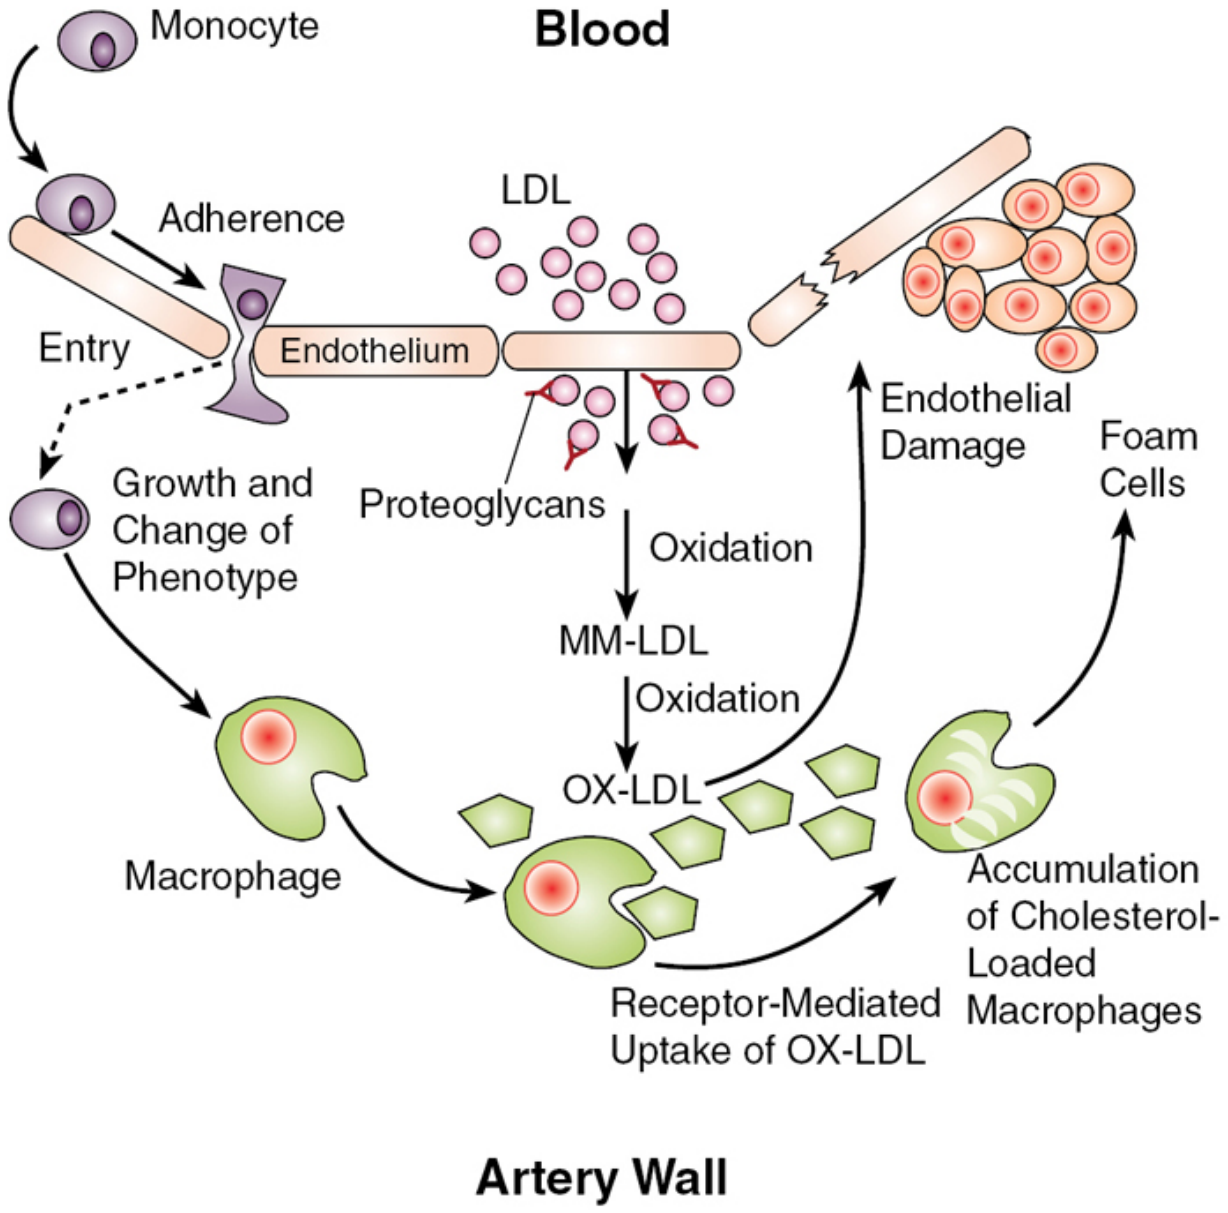

Figure 8-7 Pathogenesis of atherosclerosis and the role of oxidized LDL. LDL, low-density lipoprotein; MM-LDL, minimally oxidized low-density lipoprotein; OX-LDL, oxidized low-density lipoprotein.

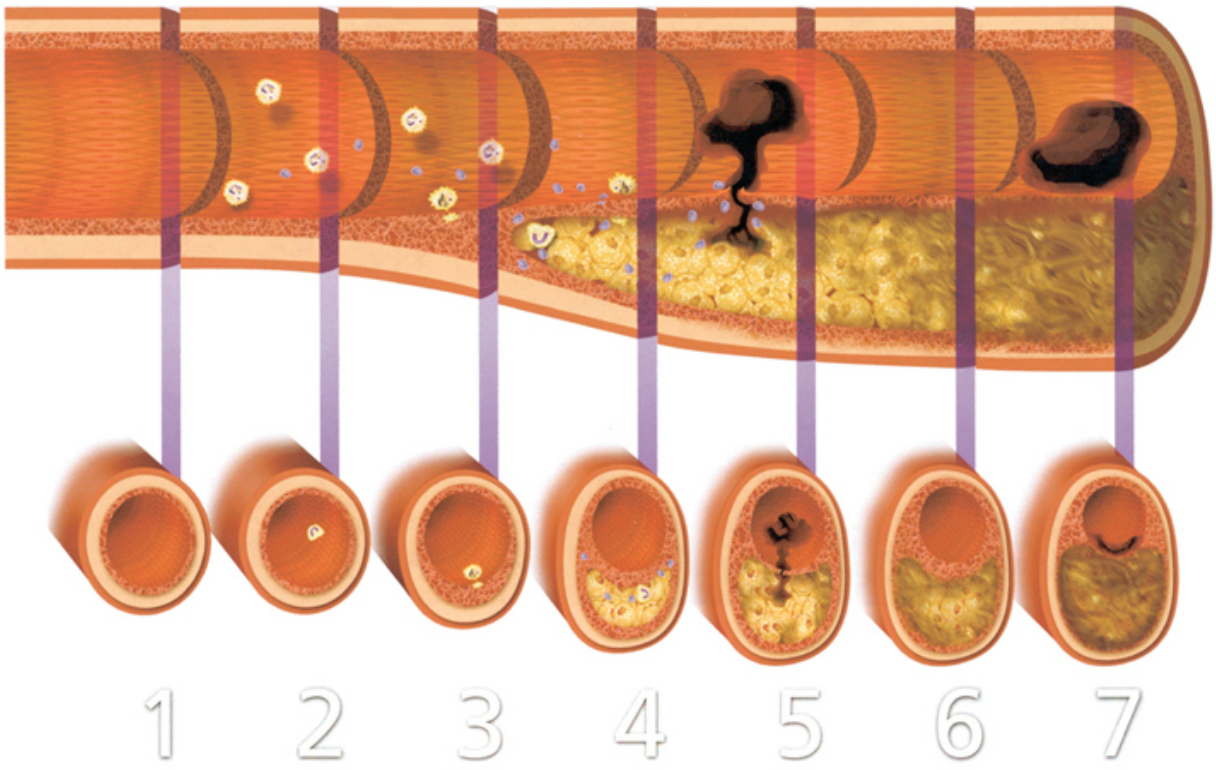

Figure 8-8 Initiation, progression, and complication of human coronary atherosclerotic plaque (numbers indicate order of progression).

Soon after taking up residence in the subendothelial space, lipoproteins are structurally modified primarily by oxidation. Modified lipoproteins stimulate dysfunctional endothelial cells to release cell adhesion molecules (intracellular adhesion molecule 1, vascular cell adhesion molecule 1, and E-selectin) and chemoattractants (monocyte chemotactic factor 1 and macrophage colony–stimulating factor), which promote adhesion and stimulate transmigration of monocytes and lymphocytes into the intimal space.[48–50] Thus, atherosclerosis is an inflammatory process in response to retained and modified lipoproteins. Once recruited, monocytes are converted to macrophages, which ingest oxidized lipoprotein particles via special scavenger or acetyl LDL receptors on the surface of macrophage cells.[51] Further engorgement with oxidized lipoproteins inhibits mobility of resident macrophages, and the cells become cytotoxic, causing further damage to the vascular endothelium. As

the uptake of modified lipoproteins into macrophage cells continues, the cells become laden with lipid and eventually become *foam cells* (**Fig. 8-8**). Monocytes and foam cells continue to secrete growth factors and cytokines, establishing a chronic inflammatory process and progression to a more complex atherosclerotic plaque.

During plaque growth, smooth muscle cells from the media migrate upward and proliferate near the luminal surface.[52] Collagen synthesis is also increased. This leads to conversion of early atherosclerotic lesions that are lipid rich with a thin fibrous cap to a potentially more stable lesion that has a small inner lipid core and more collagen and matrix proteins. At any given time, atherosclerotic lesions at various stages of development can be found all along the vascular arterial tree in high-risk patients (see **Fig. 8-7**).

As atherosclerotic lesions grow, the coronary artery remodels to accommodate the lipid-rich core. Lesions initially enlarge away from the lumen toward the media/adventitia, thus preserving the vascular lumen and ensuring normal blood flow (positive remodeling). Late in the growth of the lesion, however, the luminal space is invaded and becomes progressively narrowed as the atherosclerotic lesion progresses (negative remodeling). Inflammatory cells secrete matrix metalloproteinases that degrade collagen and fibrin produced by arterial smooth muscle cells, causing a weakened fibrous cap and a lesion more vulnerable to plaque rupture.[53] Apoptosis (cell death) of smooth muscle cells in the shoulders of the atherosclerotic cap further weakens the lesion.[54] These processes increase the chance that the atherosclerotic lesion may rupture or erode, especially at the shoulders of the lesion, and expose the underlying tissue to circulating blood elements.[55] Collagen in the exposed plaque can trigger platelet activation, and tissue factor produced by macrophages and smooth muscle cells activates the coagulation cascade. Platelets may adhere, and microthrombi may form. The resultant clot can occlude blood flow entirely, causing MI. More commonly, only partial occlusion of blood flow occurs, causing transient ischemic symptoms or unstable angina (UA). The clot creates a barrier between the underlying tissue and the circulating blood and allows healing of the plaque rupture. This process of

fissuring and rehealing appears to lead to the more complicated lesions of atherosclerosis.

Atherosclerotic lesions exist along a continuum from vulnerable lipid-rich lesions that are prone to rupture and cause a thrombosis to more stable lipid-poor, fibrin- and collagen-rich lesions. Younger atherosclerotic lesions occupy only the intimal space, whereas the older lesions may protrude into the luminal space. In fact, the culprit lesion that results in acute MI is usually not at the site of the greatest stenosis, but distal to it.[54]

CLINICAL EVALUATION AND MANAGEMENT OF ATHEROSCLEROTIC CARDIOVASCULAR DISEASE RISK

Assessment of the Standard Lipid Panel and the Role of Advanced Lipid Testing

The routine lipid panel includes standardized measurements of TC, HDL-C, and TGs. Although it is possible to measure LDL-C directly, it is common for most laboratories to calculate LDL-C. TC, HDL-C, and TGs are measured directly and then the Friedewald equation is applied to calculate LDL-C:

$$\text{LDL-C} = \text{TC} - (\text{HDL-C} + \text{VLDL-C}) \qquad \textbf{(Eq. 8-1)}$$

Because the ratio of cholesterol to TGs in VLDL is 1:5, VLDL-C is estimated by dividing the total TG level by 5. Thus, the formula is rewritten as:

$$\text{LDL-C} = \text{TC} - (\text{HDL-C} + \text{TG}/5) \qquad \textbf{(Eq. 8-2)}$$

When TGs are >400 mg/dL, the formula for estimating VLDL-C by utilizing the Friedewald equation is not accurate and, therefore, LDL-C cannot be calculated. An accurate LDL-C calculation by the

Friedewald equation also requires that the patient fast for 10 to 12 hours, which provides sufficient time for exogenous TGs, carried by chylomicrons, to be cleared from the systemic circulation. Most laboratories can measure LDL-C directly, but this is only necessary when the TG level is >400 mg/dL or the patient has not fasted. Of note, the Friedewald equation also lacks accuracy in the setting of low LDL-C. A new equation has now been developed, known as the Martin/Hopkins equation, with the primary intent to provide a more accurate estimation of LDL-C in patients with either moderately elevated TGs (140–400 mg/dL) or low LDL-C (<70 mg/dL).[56] Unlike the Friedewald equation, fasting is not required. However, the Martin/Hopkins equation does require the use of tables or an application for use. Some commercial laboratories now use this calculation rather than the Friedewald equation. The application is titled “LDL-Calculator” and is available for download from the app store. The application requires the user to input TC, HDL-C, and TGs as well as choose your preferred unit of measure. The calculator then takes over and provides an LDL-C estimate. The AHA/ACC Multisociety guideline currently recommends that LDL-C either be directly measured or the Martin/Hopkins equation be utilized in patients with an LDL-C <70 mg/dL.[5] In patients with TG levels >400 mg/dL, direct LDL-C measurement is still recommended.

In addition, in the presence of cardiometabolic disturbances including the metabolic syndrome, insulin resistance, impaired glucose tolerance, diabetes, hypertriglyceridemia, and chronic kidney disease (CKD), the calculated or direct measurement of LDL-C may not provide a complete assessment of the lipid-related CV risk. Cardiometabolic disorders are often associated with the atherogenic dyslipidemia described earlier, in which there are near-normal to modest elevations of LDL-C, reduced HDL-C levels, elevations of TGs, and an excess of atherogenic small, dense LDL particles. When LDL-C levels are near-normal to modestly elevated and the LDL particle concentration (LDL-P) is elevated, the measures are considered to be “discordant.”

There are a number of advanced lipid/lipoprotein tests to determine the concentration and/or the relative size distribution of

both LDL and HDL particles, including gradient gel electrophoresis, vertical automated profile, nuclear magnetic resonance spectroscopy, and ion mobility analysis. Data from both the Framingham Offspring Study and the Multi-Ethnic Study of Atherosclerosis demonstrated that patients with discordantly high LDL-P compared to LDL-C had higher CVD event rates, whereas patients with discordantly low LDL-P compared to LDL-C had lower CVD event rates.[57,58] CVD risk, therefore, tracked most closely with levels of LDL-P. Apo B is another measure of concentrations of atherogenic lipoproteins, including remnant VLDL particles and LDL particles, and is strongly related to CVD risk.[59]

Non–HDL-C provides a simple and easily calculated estimate of the excess CVD risk associated with the atherogenic dyslipidemia.[17] It is a single measurement of cholesterol carried by all potentially atherogenic particles, including VLDL, VLDL remnants, IDL, and LDL particles, and can give the clinician information regarding the patient's CVD risk when LDL-C cannot reliably be calculated or in the presence of excess VLDL-C and excess LDL particle concentration. Non–HDL-C is calculated by the following formula:

$$\text{Non–HDL-C} = \text{TC} - \text{HDL-C} \qquad \textbf{(Eq. 8-3)}$$

As mentioned previously, non–HDL-C can be calculated in both the fasting and the nonfasting state because VLDL-C does not need to be estimated.

Guidelines for the Management of Dyslipidemia to Reduce Atherosclerotic Cardiovascular Disease Risk

In 2018, the AHA/ACC published updated multisociety endorsed guidelines for the management of blood cholesterol to reduce ASCVD risk.[5] These guidelines have emphasized the implementation of lifestyle modifications, utilization of high-intensity statin to achieve an LDL-C reduction of least 50% in patients with ASCVD, and the consideration of nonstatin therapy for further LDL-C

reduction in very high-risk individuals with ASCVD and LDL-C >70 mg/dL. In addition, four patient groups were identified in which there is the most extensive evidence of net clinical benefit of statin therapy for the prevention of ASCVD. These patient groups include (a) individuals with clinical ASCVD, (b) individuals with primary elevations of LDL-C ≥190 mg/dL, (c) individuals ages 40 to 75 years with diabetes and LDL-C 70 to 189 mg/dL, and (d) individuals without clinical ASCVD or diabetes who are 40 to 75 years of age with LDL-C 70 to 189 mg/dL and an estimated 10-year ASCVD risk of ≥7.5%.

For each patient group, the guidelines recommend an intensity of statin therapy, either moderate or high intensity (**Table 8-3** and **Fig. 8-9**). Low-intensity statins are recommended only in patients who have experienced or are at risk for adverse effects of treatment. Measurement of the lipid panel is recommended at 4 to 12 weeks after initiation of statin therapy to assess adherence to lifestyle recommendations and medication, as well as response to therapy. Regular monitoring of the lipid panel is then recommended every 3 to 12 months as clinically indicated.

Table 8-3
Intensity of the Various Statins

High intensity (when taken as prescribed will reduce LDL-C by ≥50%)	Atorvastatin (40 mg)[a]—80 mg Rosuvastatin 20 (40) mg
Moderate intensity (when taken as prescribed will reduce LDL-C by 30%, but <50%)	**Atorvastatin 10** *(20)* **mg** **Rosuvastatin** (*5*) **10 mg** **Simvastatin 20–40 mg** **Pravastatin 40** *(80)* **mg** **Lovastatin 40 mg** *Fluvastatin XL 80 mg*

	Fluvastatin 40 mg bid **Pitavastatin 2–4 mg**
Low intensity (when taken as prescribed will reduce LDL-C by <30% on average)	*Simvastatin 10 mg* **Pravastatin 10–20 mg** **Lovastatin 20 mg** *Fluvastatin 20–40 mg* *Pitavastatin 1 mg*

The doses listed in parenthesis were not evaluated in randomized controlled trials. Bold indicates doses of statins that were evaluated in randomized controlled trials.

LDL-C, low-density lipoprotein cholesterol.

[a]Evidence is from one randomized controlled trial.

Statin Benefit Groups
Lifestyle modifications should be initiated first in all patients along with statin therapy
Age >21 years and is a candidate for statin therapy
Yes
Patient has ASCVD
Yes
Age ≤75 years
Recommendation: High-intensity statin[a]
Yes
Age >75 years or not a candidate for high-intensity statin
Recommendation: Moderate-intensity statin
Yes
Recommendation: High-intensity statin[a]
Patient has LDL-C ≥ 190 mg/dL
Yes
Recommendation: Moderate-intensity statin
Yes
Estimated 10-year ASCVD risk ≥7.5%
Recommendation: High-intensity statin
[a]Moderate-intensity statin is reasonable if patient is unable to tolerate high-intensity statin therapy
No
Estimated 10-year ASCVD risk ≥ 7.5% and age 40–75 years
Yes
Recommendation: Moderate- to high-intensity statin
Patients has diabetes (type 1 or 2) & age 40–75 years
The benefit of statins in other patient groups is less clear. Health care professionals should evaluate additional ASCVD risk factors and weigh risks, benefits, drug–drug interactions, adverse effects, and patient preferences before initiating statin therapy

Figure 8-9 Recommendations for the intensity of statin therapy based on statin benefit group diagram. ASCVD, atherosclerotic cardiovascular disease; LDL-C, low-density lipoprotein cholesterol. (Adapted from Stone NJ, Robinson JG, Lichtenstein AH, et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association task force on practice guidelines. *J Am Coll Cardiol*. 2014;63(25 Pt B):2889–2934. © 2014 Elsevier. With permission.)

For primary prevention of ASCVD, the recommended risk assessment tool is the new CV Risk Calculator based on the Pooled Cohort Equations as described in the 2013 ACC/AHA Guideline on the Assessment of Cardiovascular Risk.[5,6] The equations are derived from large, diverse, community-based cohorts that are generally representative of the U.S. population of Whites and African Americans. The calculator provides race- and sex-specific estimates of the 10-year risk of first-hard ASCVD event (nonfatal MI, CHD death, fatal or nonfatal stroke) and should be used in non-Hispanic African American and non-Hispanic Whites ages 40 to 79 years. Lifetime or 30-year risk is also provided for individuals ages 20 to 59 years who are not at high short-term risk. Variables considered in the risk calculation include age, sex, race, TC, HDL-C, systolic blood pressure (BP), treatment for hypertension, tobacco use, and diabetes. To further refine risk assessment, optional factors that may be considered include family history of premature ASCVD, high-sensitivity C-reactive protein (hs-CRP), LDL-C ≥160 mg/dL, coronary artery calcium scoring, and ankle brachial index. The National Lipid Association Patient-Centered Recommendations: Part 2 provides recommendations for risk assessment in non-Hispanic Whites and other racial and ethnic groups, which were not a part of populations used to derive the ACC/AHA Pooled Cohort Equations.[60]

Patients with a 10-year risk of ≥7.5% should be engaged in a patient–clinician discussion of the ASCVD risk reduction benefits of

statin therapy, potential adverse drug effects, potential drug–drug interactions, and consideration of patient preferences to determine whether statin therapy is appropriate (**Fig. 8-10**).

CASE 8-1

QUESTION 1: B.C. is a 46-year-old perimenopausal White female who has recently relocated to the area and is establishing care with a gynecologist. As part of her annual evaluation, a routine lipid panel is obtained. She takes no prescription medications but does take a number of dietary supplements and vitamins, including krill oil, multivitamin, B-complex, and vitamin D. She has no history of tobacco use, hypertension, or diabetes. She states she was told a number of years ago that her LDL "bad" cholesterol was elevated, but her HDL "good" cholesterol was high and no treatment was indicated. She has enjoyed jogging and spin classes, but says that as she gets older she is more fatigued and sore with exercise. She follows a Mediterranean style diet and has a glass of red wine daily.

Her father is alive at age 72 years and takes statin therapy for hyperlipidemia, though she is uncertain of the severity of his lipid disorder. He has no history of CVD. Her mother is a 71-year-old with diabetes who underwent coronary stent placement last year following the onset of angina and an abnormal stress test. She was started on statin therapy at the time of her procedure. Her brother is overweight, has hypertension and borderline diabetes, and is also on statin therapy and fenofibrate.

On physical examination, the patient has the following: normotensive (128/76 mm Hg); carotid pulses with normal amplitude and no bruits; 2/6 crescendo/decrescendo noted at the left sternal border; no abdominal bruit; peripheral pulses 2+; no tendon xanthomas, corneal arcus, or xanthelasmas.

Following a 12-hour fast, the patient's lipid panel shows the following results:

TC, 290 mg/dL
HDL-C, 56 mg/dL
LDL-C calculated, 218 mg/dL
TG, 132 mg/dL

What is your assessment of B.C.'s lipid panel results?

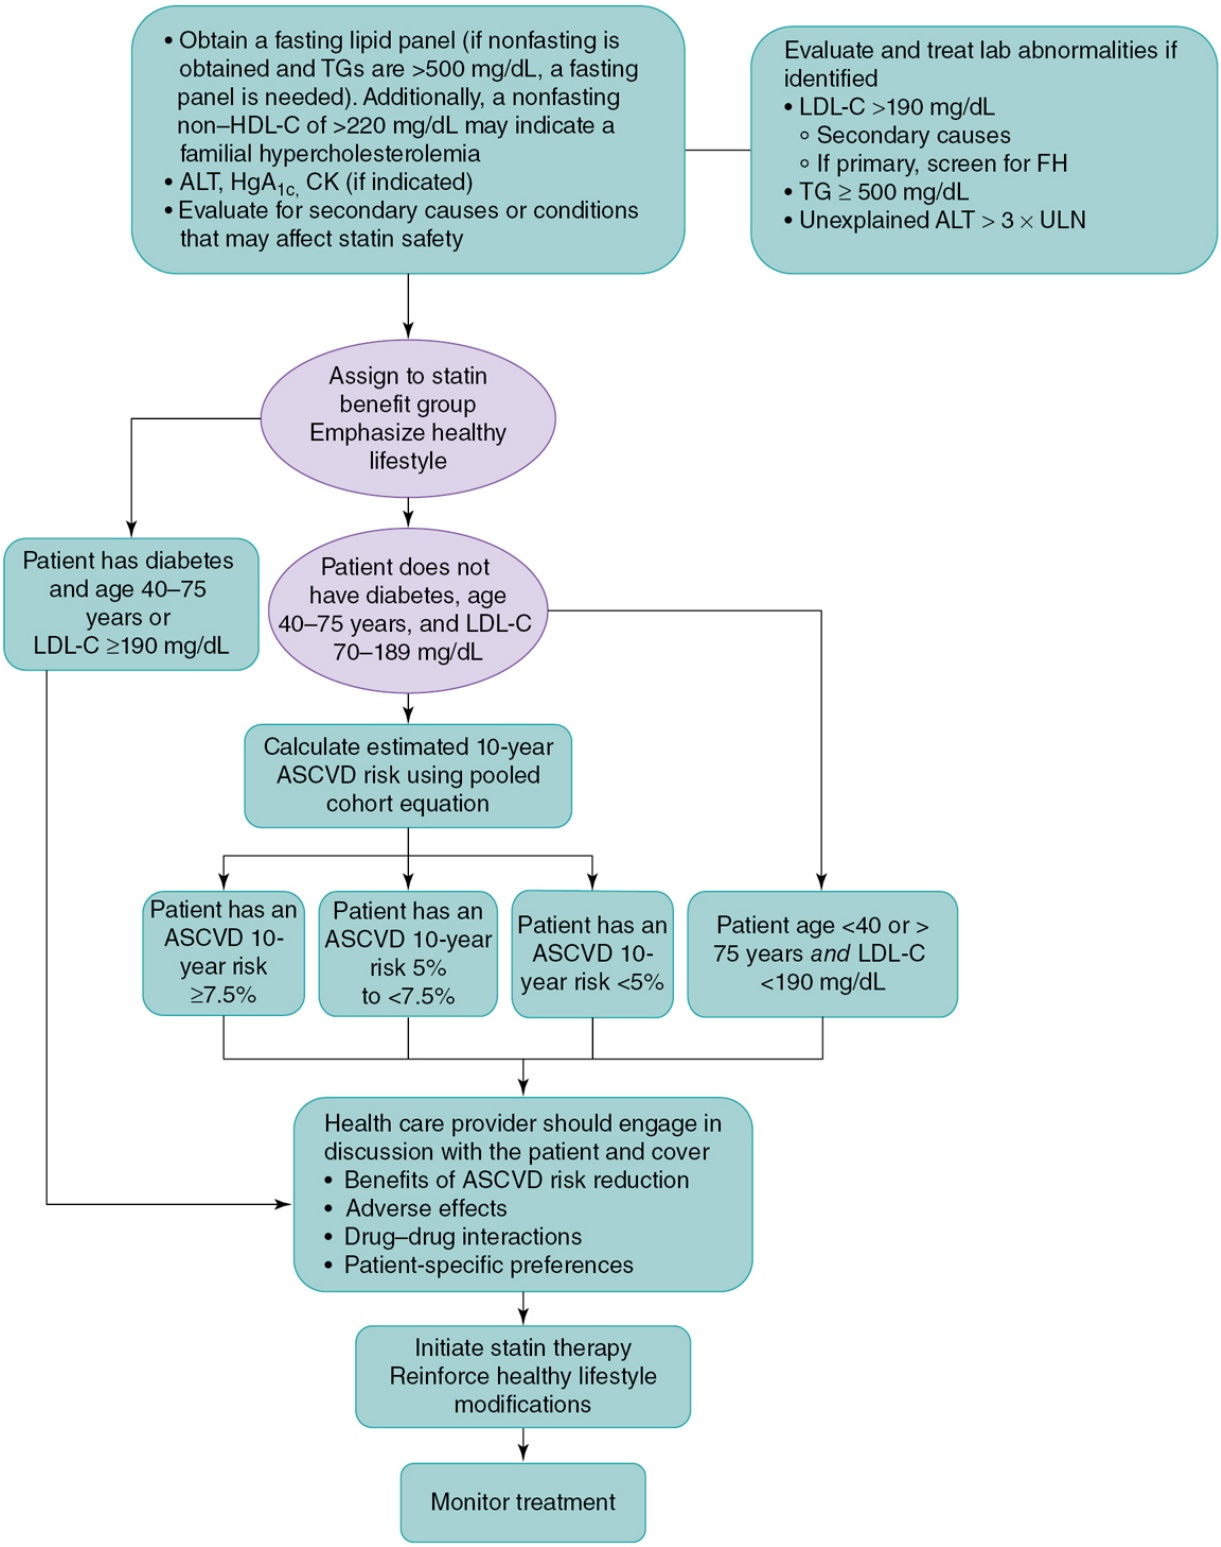

Figure 8-10 Recommendations for initiating statin therapy in patients *without* clinical ASCVD. ASCVD, atherosclerotic cardiovascular disease; HDL-C, high-density lipoprotein cholesterol;

LDL-C, low-density lipoprotein cholesterol; TG, triglycerides. (Adapted from Stone NJ, Robinson JG, Lichtenstein AH, et al. 2013 ACC/AHA guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association task force on practice guidelines. *J Am Coll Cardiol*. 2014;63(25 Pt B):2889–2934. © 2014 Elsevier. With permission.)

The patient's LDL-C is very high, and she would qualify for statin therapy as defined by the 2018 AHA/ACC Multisociety guideline recommendations for the management of hypercholesterolemia. Her HDL-C is near the average range for a female, and her TG level is considered normal (<150 mg/dL). There has been a misconception among some providers and patients that a normal or high HDL-C level is "protective" in the presence of hypercholesterolemia, based on a TC/HDL-C ratio of <3.5, and that statin therapy is not indicated. However, in the presence of very high elevations of LDL-C levels, all current and previous guidelines recommend statin therapy, regardless of baseline HDL-C.

In the presence of very high LDL-C levels, it is important to consider a number of issues before initiation of therapy. The patient's lifestyle, including diet and exercise, may play an important role in B.C.'s new diagnosis of dyslipidemia. However, she is actually quite concern with lifestyle recommendations for optimal CV health, and this is unlikely to be a factor in her lipid levels. Careful review of family history of hypercholesterolemia and ASCVD by construction of a detailed pedigree can identify patients with possible HeFH or HoFH. B.C.'s father has dyslipidemia of uncertain severity and is on statin therapy, but he has no history of premature ASCVD. Her mother developed ASCVD after age 65 years and a long history of diabetes. Statin therapy was not prescribed until her stent placement and FH is unlikely. Her brother has a mixed dyslipidemia, most likely exacerbated by overweight and poorly controlled diabetes. Thus, based on this brief pedigree, the diagnosis of FH is unlikely. Classic physical examination findings of tendon xanthomas, corneal arcus before age 45 years, and xanthelasmas are often, but not always

present in FH. B.C. does not have these findings. The patient does have a systolic murmur on cardiac examination, which may be indicative of aortic valvular disease, a very common problem in patients with HoFH.

Mean TC is typically lower in premenopausal females than in age-matched males. Premenopausal females have a less proatherogenic lipid profile with higher HDL-C levels (average 10 mg/dL) and lower LDL-C and non–HDL-C levels than age-matched males. Owing to the hormonal alterations during the perimenopausal period, LDL-C levels rise and are often higher than in age-matched males. Postmenopausal females also have a higher incidence of high TG and low HDL-C levels, with an increase in small, dense LDL particles. It is not uncommon for females without a prior history of dyslipidemia to be newly diagnosed in the perimenopausal period and B.C. may be just such a patient.

CASE 8-1, QUESTION 2: Is there any evidence for other potential causes of B.C.'s dyslipidemia?

As a routine, every patient with dyslipidemia should be evaluated for secondary causes of elevated LDL-C, non–HDL-C, or TG. Conditions that may be associated with lipid abnormalities include diabetes, CKD and nephrotic syndrome, obstructive liver disease, hypothyroidism, anorexia nervosa, polycystic ovarian syndrome, and pregnancy, among others (**Table 8-4**).[5] Average values of TC, LDL-C, HDL-C, and TG steadily rise throughout pregnancy and levels peak near full term. In uncomplicated or "normal" pregnancies, neither TC nor TG exceeds 250 mg/dL at any time during pregnancy. A number of drugs are associated with dyslipidemia or worsening of baseline lipid abnormalities, including exogenous estrogen and progesterone therapy, and a careful review of the patient's medication regimen is necessary before initiation of lipid-lowering therapy. B.C. is currently perimenopausal and does not take any medications associated with exacerbation of dyslipidemia nor any

form of exogenous hormone replacement therapy or oral contraception.

Table 8-4
Classification of Secondary Causes of Dyslipidemia

Cause	Increased LDL-C	Increased TG
Drugs/medications	Glucocorticoids, amiodarone, diuretics, cyclosporine	Hormone therapy, glucocorticoids, bile acid sequestrants, protease inhibitors, retinoic acid, anabolic steroids, tamoxifen, sirolimus, atypical antipsychotics (predominately olanzapine and clozapine), raloxifene, β-blockers, thiazide diuretics
Dietary influences	Anorexia, trans fats or saturated fats, weight gain	Very low-fat diets, weight gain, high carbohydrate intake (refined), and excessive alcohol use
Disease states	Nephrotic syndrome, biliary obstruction	Nephrotic syndrome, chronic renal failure, lipodystrophies
Disorders of metabolism	Obesity, pregnancy, hypothyroidism	Hypothyroidism, poorly controlled diabetes, pregnancy, and obesity

LDL-C, low-density lipoprotein cholesterol; TG, triglyceride.

Source: Grundy SM, Stone NJ, Bailey AL, et al. 2018 AHA/ACC/AACVPR/AAPA/ABC/ACPM/ADA/AGS/APhA/ASPC/NLA/PCNA guideline on the management of blood cholesterol: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *J Am Coll Cardiol*. 2019;73(24):3168–3209.

Case 8-1, Question 3: Further review of B.C.'s laboratory studies showed the following:

Glucose, 92 mg/dL
Alanine aminotransferase (ALT), 24 mg/dL
Aspartate aminotransferase (AST), 18 mg/dL
Creatinine, 0.9 mg/dL
Thyroid-stimulating hormone (TSH), 57 IU/mL

Laboratory evaluation has revealed that B.C.'s fatigue and muscle soreness are likely due to hypothyroidism, which has also exacerbated her previous dyslipidemia. She is placed on thyroid replacement therapy, and with normalization of her thyroid function, her follow-up laboratory results show the following:

TSH, 1.254 IU/mL
TC, 215 mg/dL
HDL-C, 59 mg/dL
LDL-C calculated, 132 mg/dL
TG, 118 mg/dL

What is the next step in the evaluation of B.C.'s ASCVD risk?

B.C. has no other ASCVD risk factors or risk equivalents other than mild dyslipidemia. Using the ACC/AHA Pooled Cohort Equations or CV Risk Calculator, her 10-year risk of ASCVD event is 0.9%. According to current guidelines, there is currently no indication for initiation of statin therapy.

The 2015 Standards of Diabetes Care of the American Diabetes Association (ADA) were revised to recommend initiation and intensification of statin therapy (high vs moderate) in patients with diabetes based on the individual patient's risk profile.[61] However, the ADA notes that the presence of diabetes confers significant risk of ASCVD and that the ACC/AHA CV Risk Estimator is of limited use in diabetics. Recommendations are made for patients younger than 40, 40 to 75, and older than 75 years of age for moderate- or high-intensity statin therapy in the presence of ASCVD risk factors or overt ASCVD (**Table 8-5**).

Table 8-5
ADA Recommendations for Statin Treatment in People with Diabetes

Age	<40 Years	40–75 Years	>75 Years
Risk factors	Zero risk factor(s) for CHD[a] Overt CHD[b]	Zero risk factor(s) for CHD Overt CHD	Zero risk factor(s) for CHD Overt CHD
Recommended dose of statin	No statin if zero risk factors Moderate or high intensity in the presence of CHD risk factor(s) High if overt CHD	Moderate if no risk factors High intensity in the presence of CHD risk factor(s) High if overt CHD	Moderate if no risk factors Moderate or high intensity in the presence of CHD risk factor(s) High if overt CHD
Recommended monitoring of lipid panel	Annually or as needed	As needed to assess for adherence	As needed to assess for adherence

Statin therapy should be initiated as an adjunct to lifestyle modifications.

CHD, coronary heart disease; LDL-C, low-density lipoprotein cholesterol.

[a]CHD risk factors include hypertension, smoking, LDL-C ≥100 mg/dL, being overweight, and obesity.

[b]Overt CHD includes those who have had a previous cardiovascular event or an acute coronary syndrome.

Adapted from Cromwell WC, Otvos JD, Keyes MJ, et al. LDL particle number and risk of future cardiovascular disease in the Framingham Offspring Study—implications for LDL management. *J Clin Lipidol*. 2007;1(6):583–592. © 2007 National Lipid Association. With permission.

The 2013 Clinical Practice Guideline for Lipid Management in CKD, published by the Kidney Disease: Improving Global Outcomes (KDIGO) Panel, notes that in non–dialysis-dependent CKD patients, the relationship between LDL-C and ASCVD events is weaker than in the general population.[62] This is likely related to lipoprotein metabolic abnormalities characterized by lower levels of LDL-C, elevated LDL-P, an increase in small dense LDL, reduced HDL-C, and elevated TG. Therefore, according to KDIGO guidelines, the measured LDL-C may be less useful as a marker of coronary risk among people with advanced non–dialysis-dependent CKD and does not serve as an indication for pharmacologic treatment. Instead, therapy is guided by the absolute risk of coronary events based on patient age and stage of CKD or estimated glomerular filtration rate (eGFR). Specific doses of individual statins are recommended for each stage of CKD or eGFR, and dose titration is not indicated. Statin therapy or combination therapy with statin and ezetimibe is not recommended in adults with dialysis-dependent CKD owing to the lack of evidence of ASCVD risk reduction in patients with stage 5 CKD. However, therapy may be continued in patients already receiving therapy at the time of initiation of dialysis (**Table 8-6**).

Table 8-6
KDIGO Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease

Chronic Kidney Disease Severity	Treatment Recommendations
Age ≥50 years of age with eGFR <60 mL/min/1.73 m^2 not on HD or have a history of kidney transplant	Statin or statin/ezetimibe combination
Age ≥50 years with CKD and eGFR >60 mL/min/1.73 m^2	Statin
Age 18–49 years with CKD not on HD or history of kidney transplant with one or more of the following ▪ Diabetes mellitus ▪ Prior stroke ▪ Known CAD ▪ Estimated 10-year risk of CAD death or nonfatal MI >10%	Statin
Dialysis-dependent CKD	No initiation of therapy

CHD, coronary heart disease; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; HD, hemodialysis.

Adapted from Kidney Disease: Improving Global Outcomes (KDIGO) Lipid Work Group. KDIGO clinical practice guideline for lipid management in chronic kidney disease. *Kidney Int Suppl*. 2013;3(3):259–305. © 2013 International Society of Nephrology. With permission.

CASE 8-2

Question 1: S.W. is a 51-year-old African American male with CKD due to polycystic kidney disease. He has no history of tobacco use or diabetes, but is treated for hypertension. He is very active and works in landscape maintenance, but does not have a program of consistent aerobic exercise. He follows a heart-healthy diet consistent with the DASH (Dietary Approaches to Stop Hypertension) recommendations and has maintained a normal body mass index (BMI). He is referred for nephrology consultation and the following results are obtained:

eGFR, 42 mL/min
TC, 187 mg/dL
HDL, 39 mg/dL
LDL-C calculated, 102 mg/dL
TG, 230 mg/dL
$HgbA_{1c}$, 6.8%
BP, 126/68 mm Hg

What is your assessment of S.W.'s ASCVD risk and his lipid panel results?

S.W. has stage 3b CKD defined as an eGFR between 30 and 44 mL/min/1.73 m^2. The ACC/AHA Multisociety guidelines identify CKD as a risk-enhancing factor and recommend initiation of moderate-intensity statin or moderate-intensity statin combined with ezetimibe in those ages 40 to 75 years with an LDL-C 70 to 189 mg/dL who have a 10-year ASCVD risk of 7.5% or higher.[5]

CASE 8-2, QUESTION 2: Would this patient require treatment at this time?

The 2013 KDIGO Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease provides guidance on lipid management and treatment for all patients with CKD (non–dialysis dependent, dialysis dependent, kidney transplant recipients, and children). According to KDIGO experts, in patients with CKD who are non–dialysis dependent, the relationship between LDL-C and ASCVD events is weaker than in the general population likely related to the atherogenic dyslipidemia characteristic in CKD. Thus, the measured LDL-C does not serve as an indication for treatment. KDIGO guidelines recommend that lipid therapy be guided by the absolute risk of coronary events based on patient age and stage of CKD or eGFR, regardless of baseline lipids. Statin or statin/ezetimibe therapy is recommended in non–dialysis-dependent adults age 50 years or older with eGFR <60 mL/min/1.73 m^2. In adults age 50 years or older with CKD and eGFR ≥60 mL/min/1.73 m^2, only statin therapy is recommended. In adults ages 18 to 49 years with CKD but not treated with chronic dialysis or kidney transplantation, statin treatment is suggested if one of the following is present: known CHD (MI or coronary revascularization), diabetes mellitus, prior ischemic stroke, or estimated 10-year incidence of coronary death or nonfatal MI >10% by the Framingham Risk Score. Statin therapy is also recommended in adult kidney transplant recipients. Therefore, according to KDIGO guidelines as well as

other treatment guidelines, S.W. may be treated with statin or statin/ezetimibe therapy.

PHARMACOLOGIC THERAPY

3-Hydroxy-3-Methylglutaryl Coenzyme A Inhibitors (Statins)

MECHANISM OF ACTION

Statins competitively inhibit HMG-CoA reductase, the enzyme responsible for converting HMG-CoA to mevalonate in an early, rate-limiting step in the biosynthetic pathway of cholesterol (**Fig. 8-11**; also see **Fig. 8-1**). This causes decreased production of mevalonate and its subsequent conversion to cholesterol and a subsequent compensatory increase in the synthesis of LDL receptors. The increased LDL receptor density results in an increase in hepatic update of LDL-C, and to a lesser extent VLDL particles, and significantly lower levels of plasma LDL-C. In addition to the reduction in LDL-C, statins also reduce apo B, TG, and TC concentrations.[63–67]

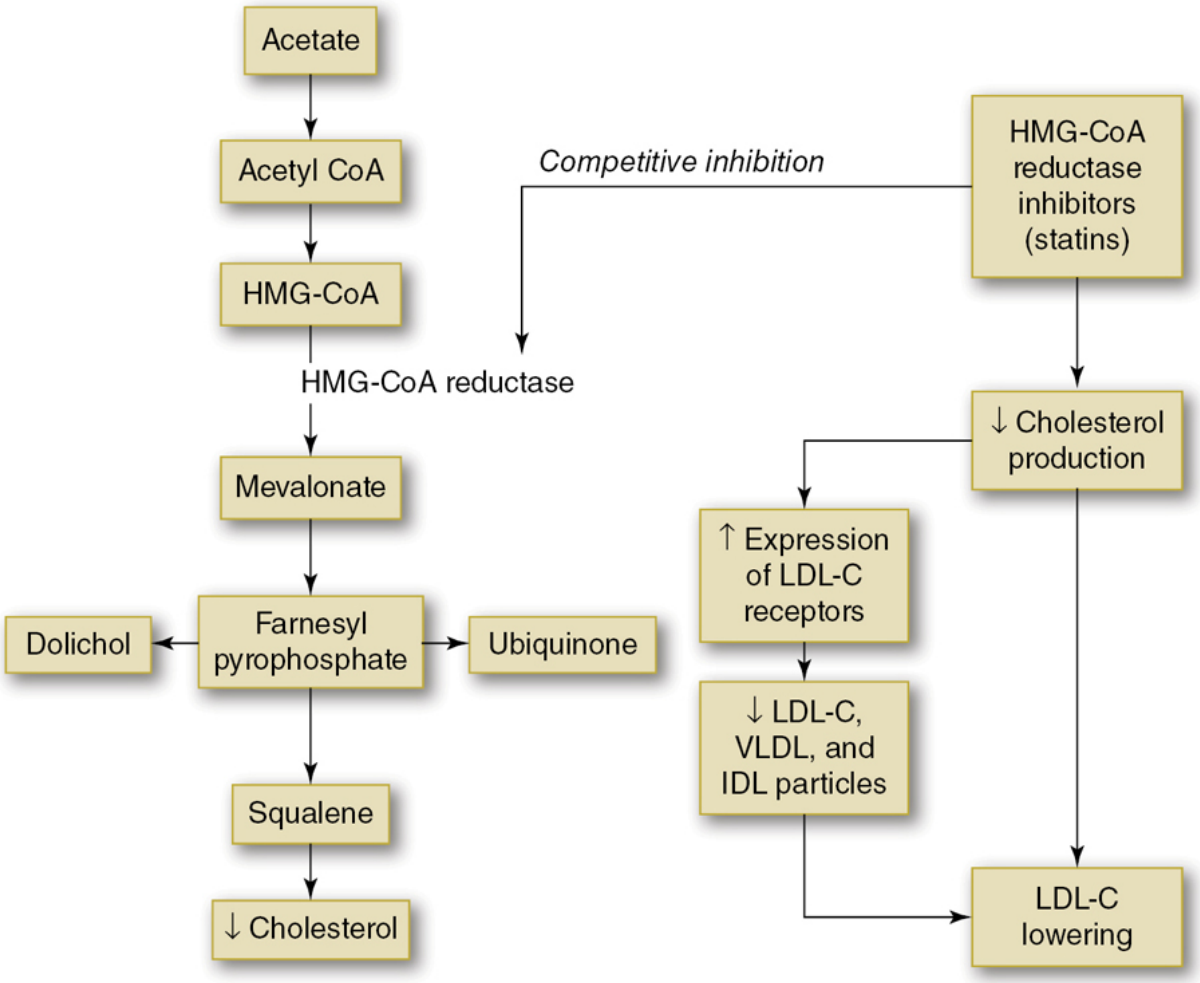

Figure 8-11 Reaction catalyzed by HMG-CoA reductase. Acetyl-CoA, acetyl coenzyme A; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; IDL, intermediate-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; VLDL, very low-density lipoprotein.

EFFICACY

Lipid-lowering therapy for patients with ASCVD is now accepted as standard of care.[5] Beginning in the mid-1990s, the results of clinical trials with more potent statins were reported. Five of these (Scandinavian Simvastatin Survival Study [4S], Cardiovascular and Recurrent Events [CARE], the Long-Term Intervention with Pravastatin in Ischemic Disease Study [LIPID], Treating to New Targets [TNT], and Incremental Decrease in End Points through Aggressive Lipid Lowering [IDEAL]) were secondary prevention trials

conducted in patients with known CHD.[68–72] In 4S, CARE, and LIPID, CHD death and nonfatal MI occurred in 13% to 22% of placebo-treated patients in the 5-year follow-up period, compared with event rates of 10% to 14% with patients on statin therapy.[68–70] Total mortality was reduced significantly in two of these trials, 4S and LIPID, that were powered to assess total mortality. In addition, fewer revascularization procedures were required in patients receiving statin therapy and 31% fewer strokes occurred.[73] The TNT and IDEAL trials demonstrated additional CV benefit for high-intensity versus moderate-intensity statin therapy in patients with stable CHD. These trials randomly assigned patients to receive either high-dose atorvastatin 80 mg versus atorvastatin 10 mg or simvastatin 20 mg with an approximate follow-up period of 5 years. In both trials, more intensive lowering of LDL-C to significantly <100 mg/dL was associated with a reduction in CHD.[71,72] The further reductions in the incidence of heart attacks, revascularizations, and ischemic strokes with more intensive lowering of LDL-C with statins compared with less intensive statin regimens were verified in a recent meta-analysis of randomized trials. An additional 38.6-mg/dL reduction of LDL-C in patients on high-intensity therapy was associated with a 38% relative reduction in major vascular events ($P < .0001$).[73]

The Heart Protection Study (HPS)[74] extended the results of earlier secondary prevention statin trials (4S),[68] CARE,[69] and LIPID.[70] The HPS included 20,536 patients with a history of CHD or cerebrovascular disease (stroke or transient ischemic attacks), peripheral vascular disease, or diabetes not considered by their general practitioner to have a clear indication for statin therapy because of relatively low baseline cholesterol levels (mean LDL-C 131 mg/dL).[74] A reduction in CHD events was achieved in both males and females; in all age groups, including those ages 75 to 85 years; and regardless of the baseline LDL-C, including those with initial levels <100 mg/dL.

Trials in patients with acute coronary syndrome (ACS) have also demonstrated CHD risk reduction. The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) study randomly assigned patients presenting to the hospital with UA or

non–Q-wave MI to statin therapy or placebo for 4 months. This resulted in a 24% reduction in symptomatic ischemia requiring emergency hospitalization and a 60% reduction in nonfatal strokes in those receiving the statin.[75,76] More recently, the Pravastatin or Atorvastatin Evaluation and Infection Therapy—Thrombolysis in Myocardial Infarction (PROVE-IT) is considered a landmark trial that demonstrated superior CV event lowering when high-intensity statin therapy (atorvastatin 80 mg) was implemented within 10 days of ACS versus moderate-intensity (pravastatin 40 mg) statin therapy.[77] After 2 years of treatment, mean LDL-C levels in patients randomly assigned to receive atorvastatin 80 mg and pravastatin 40 mg were 62 and 95 mg/dL, respectively. The composite CV end point (death from any cause, MI, documented UA requiring rehospitalization, revascularization, and stroke) was significantly reduced by 16% with high-intensity atorvastatin compared with moderate-intensity pravastatin.[77] Data from the National Registry of Myocardial Infarction 4 demonstrated that early initiation of statins in the acute setting (with the first 24 hours of an acute MI) was associated with a significantly lower rate of early complications and in-hospital mortality.[78] In addition, discontinuation of statin in patients who present with an ACS is associated with increased event rates above those who are statin naive.[79,80]

PHARMACOKINETICS/PHARMACODYNAMICS

The currently available statins are atorvastatin, fluvastatin, lovastatin, pitavastatin, pravastatin, rosuvastatin, and simvastatin. These agents possess different pharmacokinetic properties that may play a role in their efficacy and safety.

Three statins are derived from fungi (simvastatin, pravastatin, and lovastatin),[81–83] whereas the others (atorvastatin, rosuvastatin, pitavastatin, and fluvastatin) are synthetic.[84–87] Lovastatin and simvastatin are prodrugs and must be converted to their active form to exert a pharmacologic effect. Rosuvastatin and atorvastatin have the longest half-lives of 19 and 14 hours, respectively, which enables longer inhibition of the HMG-CoA enzyme and greater LDL-C

reductions compared to other agents.[84,86] Both of these agents lower LDL-C by a mean of ~60% at maximum doses (rosuvastatin 40 mg daily and atorvastatin 80 mg daily). The long half-life also allows for administration at any time of day rather than at bedtime for maximum effect, which is recommended for simvastatin, lovastatin, pravastatin, and fluvastatin.[81–83,85] Although pitavastatin has a shorter half-life (12 hours) than rosuvastatin and atorvastatin, it may also be taken at any time of day.[84,86] The administration of the shorter acting agents at bedtime is important because cholesterol biosynthesis occurs at its highest rate in the evening hours, thus allowing these agents to have the greatest effect on HMG-CoA reductase inhibition and on lowering of LDL-C. However, with extended-release (ER) formulations of lovastatin and fluvastatin, bedtime administration is less important.[81–88]

The amount of statin that reaches the systemic circulation is relatively small. Bioavailability ranges from <5% with lovastatin and simvastatin to 51% with pitavastatin (oral solution). Pravastatin, fluvastatin, and rosuvastatin are hydrophilic agents and may have less tissue distribution and result in less muscle toxicity. However, this aspect is more theoretical than it is clinically valid. All statins are eliminated primarily by the liver, with substantial biliary excretion. However, several statins require dose adjustments in patients with significant renal insufficiency (**Table 8-7**).[81–88]

Table 8-7

Dosing of Statins in Patients with Renal Insufficiency

Statin	Creatinine Clearance 30–50 mL/min	Creatinine Clearance 15–29 mL/min	Creatinine Clearance <15 mL/min or on Hemodialysis
Atorvastatin	Doses up to 80 mg may be used	Doses up to 80 mg may be used	Doses up to 80 mg may be used
Fluvastatin	Doses up to 80 mg may be used	Doses up to 40 mg may be used	Doses up to 40 mg may be used
Lovastatin	Doses up to 80 mg may be used	Doses up to 40 mg may be used	Doses up to 40 mg may be used
Pitavastatin	Doses up to 2 mg may be used	Doses up to 2 mg may be used	Doses up to 2 mg may be used
Pravastatin	Doses up to 40 mg may be used	Doses up to 40 mg may be used	Doses up to 40 mg may be used
Simvastatin	Doses up to 80 mg may be used	Doses up to 20 mg may be used	Doses up to 20 mg may be used
Rosuvastatin	Doses up to 40 mg may be used	Doses up to 10 mg may be used	No data

ADVERSE EFFECTS

Statins are generally well tolerated. The most common adverse effects reported include muscle pain and weakness (myalgias); headache; gastrointestinal (GI) symptoms, including dyspepsia, flatus, constipation, and abdominal pain; and skin rashes.[81–91] These symptoms are usually mild and often dissipate with continued therapy. Less common adverse effects include myopathy, elevated hepatic transaminases, and diabetes. Cognitive dysfunction may be potentially associated with statin therapy, but this has not yet been demonstrated to be causally related to statin treatment.

Muscle-related adverse effects associated with statins are divided into three different types based on symptoms and the presence or absence of creatine kinase (CK) elevations. These include myalgias, myopathy, and rhabdomyolysis. Myalgias are the most commonly reported muscle symptoms with an incidence of around 32%.[92] Myalgias are defined as muscle aches or weakness without CK elevations. This adverse effect is the most common reason for patients to discontinue statin therapy.[92]

Myopathy is defined as the presence of myalgias, including aches, soreness, or weakness, and an increase in serum CK >10 times the upper lipid of normal (ULN). Myopathy occurs in ~0.1% to 1% of patients and is a dose-dependent effect. If myopathy is present, a careful history is necessary to rule out usual causes (ie, trauma, increased physical activity). Rhabdomyolysis is defined as a CK of at least 10 times the ULN with an elevated serum creatinine and symptoms requiring treatment.[93] Rhabdomyolysis is the least common of the muscle-related adverse effects, but can be life-threatening with acute renal failure, cardiac arrest, or arrhythmias due to severe electrolyte abnormalities. Most cases of rhabdomyolysis have occurred with high doses of statins, in patients

with impaired renal or hepatic function, in older individuals, or when statins are used in combination with interacting drugs. The most common areas affected are in the belly of larger muscles. It is important to distinguish between this and joint pain that may be associated with arthritis.

Simvastatin at a dose of 80 mg daily is associated with the highest incidence of rhabdomyolysis among the statins agents. However, this dose is no longer recommended by the U.S. Food and Drug Administration (FDA) or the 2018 AHA/ACC Multisociety cholesterol guideline.[5,81]

Management of statin-associated muscle adverse effects can be challenging. Routine monitoring of CK levels in asymptomatic patients is unnecessary. However, unexplained symptoms of muscle aches, weakness, or soreness should prompt evaluation of CK and other potential underlying etiologies. Myopathy is more likely to occur with high systemic concentrations of statin and when there are underlying risk factors (eg, age older than 80 years, severe CKD, hypothyroidism, trauma, interacting medications, or flulike syndromes). If a patient develops signs and symptoms consistent with myopathy, statin therapy should be withdrawn until CK levels return to normal. If rhabdomyolysis is diagnosed, statin therapy should be discontinued immediately and etiology determined. Rechallenge of a statin may be considered if the cause was secondary to an interacting medication or other underlying cause that can be identified and corrected. Occasionally, symptoms of myalgia are bothersome or intolerable to the patient, even when the CK level is normal or elevated <10 times the ULN. In these cases, the statin should be discontinued. Once symptoms subside, statin therapy can be restarted at the same or reduced dose, or with a different statin. Alternate-day and even once-weekly dosing of statins have been used in patients who have statin intolerance caused by myopathy.[94] However, these alternative regimens have not been evaluated in CV outcome trials.

Statins may also cause an elevation in transaminase enzyme levels of more than three times the ULN in 1% to 1.5% of patients in a dose-dependent manner. The transaminase level will often return

to normal spontaneously in 70% of cases, even with continued statin therapy.[93] Elevations in transaminases will also return to normal if the statin is discontinued. A rechallenge with the same or a different statin after enzymes have returned to normal limits is acceptable. If the medication is tolerated on rechallenge, it can be continued; recurrence of transaminase elevation warrants further evaluation of other potential causes. It is recommended that before initiating statin therapy, patients should have baseline liver function tests (LFTs) performed. The report of the NLA Statin Safety Task Force recommends that if ALT or AST is one to three times the ULN during statin therapy, there is no need to discontinue the statin.[93] If ALT or AST exceeds three times the ULN during statin therapy, monitor the patient and repeat the transaminase measures. There is no need to discontinue the statin. If a patient's transaminase levels continue to rise or if there is further objective evidence (ie, hepatomegaly, jaundice, elevated direct bilirubin, related symptoms) of liver injury, the statin should be discontinued. The estimated incidence of statin-associated liver failure is 1 per million person-years of use.[95] There is evidence that patients with chronic liver disease, nonalcoholic fatty liver disease, or nonalcoholic steatohepatitis may safely receive statin therapy.[96]

In 2012, the FDA required an update to the statin prescribing labeling to include information regarding a potential increased risk of reversible cognitive impairment, to include memory loss. Some case reports have suggested that the statins may cause cognitive impairment or memory loss.[97] However, data from randomized controlled trials have failed to show an association, and some data even suggest a beneficial effect on the progression of Alzheimer disease.[74,98,99] Therefore, if a patient presents with cognitive deficits, he should first undergo an evaluation to identify other potential causes. If the statin is suspected, it is reasonable to consider discontinuing therapy for up to 3 months and monitor for improvement.[93] If improvement is noted, then a speculation may be made that the statin was the cause. However, one must carefully balance the decision to discontinue the statin due to the proven benefit of these agents. Consideration should be given to perhaps

reintroduce a different statin or a different statin dose and monitor for recurrence of deficits. In addition, because improvement in cognitive function is subjective, an objective test such as a Mini Mental State Examination (MMSE) should be considered before discontinuation and repeated after discontinuation to assess for any changes.

CASE 8-3

QUESTION 1: M.T. is a 56-year-old White female who presents for new patient evaluation with a 10-year history of type 2 diabetes and hypertension. Current medications include metformin, lisinopril, and chlorthalidone. She currently smokes about 1/2 pack of cigarettes/day, but is considering a quit date. She reports that she struggles with weight management (BMI 33.8 kg/m^2) and has difficulty with exercise due to previous knee injury and a torn rotator cuff. She has a strong family history of premature ASCVD, diabetes, hyperlipidemia, and obesity. Her father underwent coronary artery bypass grafting at age 51 years. Her mother suffered a mild stroke at age 62, but has no residual deficits. She has four siblings of which two have known CHD. On physical examination, her BP is 148/88; bilateral carotid bruits; cardiac examination unremarkable; abdominal bruit; peripheral pulses 1+ bilaterally; no tendon xanthomas, corneal arcus, or xanthelasmas. Her initial laboratory results demonstrate the following:

TC, 273 mg/dL
HDL-C, 43 mg/dL
LDL-C, 158 mg/dL
TGs, 360 mg/dL
$HgbA_{1c}$, 8.2%

What are your initial recommendations for lipid management for M.T.?

All available guidelines for the management of dyslipidemia and diabetes recommend lifestyle counseling as the foundation of therapy. M.T.'s BMI is consistent with obesity, and she has inadequately controlled diabetes and hypertension. Nutrition counseling and weight management will be critical to improve control of these important ASCVD risk factors. Tobacco cessation counseling, referral to a cessation program, and possible pharmacotherapy and/or nicotine replacement therapy are important in this very high-risk patient with a strong family history of premature ASCVD. Given the patient's ongoing knee and shoulder pain, her

ability to engage in significant aerobic activity may be limited until successful weight loss is achieved.

According to the 2018 AHA/ACC Multisociety and ADA guideline recommendations for the management of dyslipidemia, M.T. qualifies for statin therapy in a high-risk diabetic. Her 10-year ASCVD risk by the ACC/AHA CV Risk Calculator is 27.2% and high-intensity statin is, therefore, indicated. Patients with diabetes and two or more other major ASCVD risk factors are considered to be at very high risk and lipid-lowering therapy is recommended. The ADA recommends statin therapy in all patients between the ages of 40 and 75 with type 1 or type 2 diabetes. The 2018 AHA/ACC Multisociety guidelines recommend a reduction in LDL-C by ≥50%.[5] The intensity of statin therapy is based upon the patient's 10-year ASCVD risk by the ACC/AHA CV Risk Calculator. High-intensity statin is considered reasonable in patients with 10-year risk ≥7.5%. Thus, the recommendation for high-intensity statin therapy for M.T. is consistent across all U.S. guidelines.

Case 8-3, Question 2: M.T. is started on atorvastatin 40 mg but, within the next 3 months, returns to clinic with joint and muscle symptoms, noting that her knees and shoulder are more painful. How would you approach the evaluation of possible statin-related muscle symptoms?

Statin-related muscle symptoms present a significant challenge to clinicians, though the prevalence of true statin intolerance is likely quite low. A systematic approach to possible statin intolerance is required to confirm the diagnosis, particularly in a very high-risk patient like M.T. The AHA/ACC Multisociety guideline and NLA provide similar strategies for patient evaluation and management, and these recommendations have been incorporated into the ACC Statin Intolerance App for all mobile devices as well as a web-based version.

It is important for clinicians to take a careful musculoskeletal history and review of systems and document patient ailments before initiation of statin therapy. As reported by M.T., patients may report baseline muscle and joint symptoms that have varied in severity and

frequency before lipid management. Following initiation of statin therapy, patient's muscle symptoms should be compared to those at baseline evaluation to determine whether symptoms are new or merely coincidental exacerbations of prior existing ones. True statin-related myalgias are typically symmetric and are described as aching, soreness, stiffness, tenderness, weakness, or cramping of large proximal muscle groups. Tingling, numbness, sharp or stabbing pain, twitching, nocturnal cramps, arthralgias/arthritis, or unilateral symptoms are less likely to be statin related. Clinicians should consider factors that may increase the risk for statin-related muscle symptoms, such as heavy exercise or exertion, dehydration, substance abuse, frailty, low BMI, female gender, multiple or serious comorbidities, renal insufficiency, hepatic dysfunction, or drug interactions. Other potential primary causes of muscle symptoms should be evaluated, such as hypothyroidism, vitamin D deficiency, trauma, previous or new primary muscle diseases, rheumatologic disorders, metabolic disorders (adrenal insufficiency, hypoparathyroidism, Cushing syndrome), or PAD.

CASE 8-3, QUESTION 3: What recommendations would you give the patient regarding continuation of statin therapy?

Both the AHA/ACC Multisociety guidelines and NLA guidelines recommend temporary discontinuation of statin when a patient reports muscle symptoms that they believe are related to treatment. Statin-related symptoms usually resolve within a few days to 2 weeks, though there have been rare case reports of persistent myopathy following discontinuation of statin therapy. When symptoms have resolved and the patient is asymptomatic, treatment with the same statin at original or lower dose is reinitiated to determine whether the symptoms are definitively related to statin. If muscle symptoms recur, it is assumed that symptoms may be related to drug therapy and that statin should be discontinued. Most algorithms for evaluation and management of possible statin intolerance recommend a trial of at least two to three statins, with

discontinuation and rechallenge if the patient again reports muscle-related symptoms.

The seven currently available statins differ in metabolism, half-life, and lipophilicity, and some providers recommend that the second (or third) statin prescribed in a patient with possible statin intolerance be chosen based on characteristics that differ from the initial agent. There is no trial evidence that this strategy is effective. There have been a number of smaller trials evaluating the potential benefits of ubiquinone or coenzyme Q10 in patients with possible statin-related muscle symptoms, but the results have been inconsistent.

If a patient has failed a systematic challenge/rechallenge approach with two to three statins, guidelines suggest consideration of nonstatin therapies, such as ezetimibe, BASs, or PCKS9 inhibitors.[100]

DIABETES

Statins have been associated with an increased risk of type 2 diabetes. A review of 13 trials involving 19,140 patients showed a 9% relative increased risk for the incidence of diabetes in those taking statins compared to placebo. This equates to approximately one new case of diabetes for every 255 patients treated over a 4-year period.[101] A meta-analysis of five trials comparing high-dose versus low-dose statins showed a 12% increased relative risk for incident diabetes over a 2- to 5-year follow-up in those patients who received higher doses of statins.[102] Based on the data, there appears to be an increased risk of developing diabetes, albeit small. However, owing to the demonstrated clinical benefit of statin therapy, the benefit clearly outweighs the risk of developing diabetes, and statin therapy should not be avoided because of the concern for this adverse effect.

Overall, the incidence of adverse effects with statins varies, with myalgia being the most common. When choosing a statin as well as a statin dose, one must consider the various pharmacokinetic characteristics of that statin, the patients' comorbid conditions, and concomitant medications to minimize risk.

PLACE IN THERAPY

Statins are considered a first-line pharmacologic therapy for the prevention of ASCVD events. They have demonstrated significant reductions in morbidity and mortality across many patient populations.[68–72,103,104] Statin therapy should be initiated before or simultaneously with therapeutic lifestyle modifications.[5]

The initial dose of statin is determined by certain criteria that then place them into any of the four statin benefit groups. The criteria are based on age, the presence or absence of ASCVD, the presence or absence of diabetes, LDL-C level, and their estimated risk based on the Pooled Cohort Equation.[5] High-intensity statin therapy is recommended in the following patient populations: patients younger than 75 years who have clinical ASCVD, patients older than 21 years and an LDL-C of >190 mg/dL, and patients with diabetes (type 1 or type 2) ages 40 to 75 years with an estimated 10-year ASCVD risk of >7.5%. Moderate-intensity therapy is recommended in patients older than 75 years if not a candidate for high intensity, LDL-C >190 mg/dL (if not a candidate for high intensity), type 1 or type 2 diabetes and ages 40 to 75 years, and a 10-year ASCVD risk of >7.5% and ages 40 to 75 years. The later population may be initiated on high-intensity therapy if clinically indicated. The intensity of doses of the various statins is outlined in Table 8-3.[5] Of note, in patients with LDL-C >190 mg/dL, combination therapy with a nonstatin agent may be needed to achieve additional LDL-C lowering if desired.

There are two patient populations for which there are limited data on the benefit of statin therapy: patients with ASCVD and heart failure (HF) (New York Heart Association Class II–IV) and patients on chronic hemodialysis. There are currently no recommendations to initiate statin therapy in these patient populations.[5]

In addition to their ability to lower LDL-C, statin also have many “pleiotropic” effects that play a role in patients with ASCVD, independent of their ability to lower LDL-C. These effects include improvement in endothelial function, plaque stabilization, antithrombotic effects, anti-inflammatory, antioxidant effects,

increased nitric oxide bioavailability, and reduced plaque progression.[105]

Although well demonstrated as beneficial in patients with established CHD, this benefit in primary prevention is less well defined. In patients without CHD, statins have not been shown to reduce mortality. They have demonstrated a lowering of future vascular events over a time frame of 5 to 10 years, albeit small. As a result, prescribing statins in patients without ASCVD but ages 40 to 75 years with an estimated ASCVD risk of ≥7.5% remains controversial.

DRUG INTERACTIONS

Drug interactions with statins that result in higher blood levels of the statin or an active metabolite can increase the risk of myositis. Statins that depend on the cytochrome P-450 (CYP) 3A4 enzyme system to be metabolized are most vulnerable to this interaction (ie, lovastatin, simvastatin, and, to a lesser extent, atorvastatin). Fluvastatin is primarily a substrate of the 2C9 isoenzyme and, to a lesser extent, 2C8 and 3A4 and, therefore, is more vulnerable to interactions with drugs that directly inhibit CYP2C9 or act as competitive inhibitors (substrates) for this alternative system. Pravastatin, pitavastatin, and rosuvastatin are not extensively metabolized by the CYP enzyme system.[85–87] Rosuvastatin is metabolized minimally (about 10%), with CYP2C9 and CYP2C19 being the primary isoenzymes involved. Pitavastatin is marginally metabolized by CYP2C9 and, to a lesser extent, by CYP2C8. The major metabolite in human plasma is lactone, which is formed via glucuronidation by uridine 5′-diphospho-glucuronosyltransferases UGTA3 and UGT2B7. Pravastatin undergoes isomerization in the gut to a relatively inactive metabolite. Variability of gastric metabolism has been shown to be associated with the LDL-C-lowering effects of pravastatin.[106] Therefore, rosuvastatin and pravastatin have the lowest potential for interaction with medications that inhibit the CYP metabolic pathways. Some of the most commonly encountered medications that interact with statins by inhibiting the CYP3A4

enzyme system are azole antifungals (itraconazole, ketoconazole, and miconazole), certain calcium channel blockers (diltiazem and verapamil), macrolide antibiotics (clarithromycin and erythromycin), protease inhibitors (eg, ritonavir), grapefruit juice (>1 quart), cyclosporine, and antidepressants (nefazodone). Drugs that are substrates for the CYP3A4 system include certain benzodiazepines (alprazolam, midazolam, triazolam), calcium channel blockers (especially diltiazem), carbamazepine, cyclosporine, estradiol, felodipine, loratadine, and quinidine. When these substrate drugs are used together with simvastatin or lovastatin (and to a lesser extent atorvastatin), systemic blood levels of the statin may be increased because of competitive inhibition of the CYP3A4 enzymes, and this may increase the risk for myositis.

Added caution should also be exercised when adding gemfibrozil with a statin to treat patients who also have elevated TG levels. Gemfibrozil interferes with the glucuronidation of statins, thereby interfering with their renal clearance. This impact may be minimal or up to a threefold to fourfold increase in statin levels depending upon the specific agent.[107–116] Owing to the significance of this interaction, fenofibrate is the preferred fibric acid derivative to use in combination with statins. However, gemfibrozil may be used in combination with certain statins if clinically indicated.[86,109–114,117,118] A list of select statin drug interactions is presented in **Table 8-8**.

Table 8-8
Select Drug Interactions With Statins

	Contraindicated Medications	Medications With Dose Limits	Maximum Dose of Statin When Used in Combination

CASE 8-4

QUESTION 1: J.G. is a 63-year-old White female who implemented lifestyle modifications for her dyslipidemia 7 months ago and is in clinic for follow-up. She has a history of gout, chronic nonischemic HF (left ventricular ejection fraction [LVEF] 26%), and diabetes (diet controlled) as well as a 20 pack-year smoking history (quit 5 years ago). Her medications include lisinopril, furosemide, and metoprolol succinate 25 mg once daily. Her vital signs include BP 124/80 mm Hg and heart rate 75 beats/min. Her laboratory results are as follows: HDL-C 64 mg/dL, LDL-C 101 mg/dL, TG 98 mg/dL, and TC 185 mg/dL.

What is her 10-year ASCVD risk based on the calculator?

CASE 8-4, QUESTION 2: Based on her risk, what is the most appropriate next step for J.G.?

CASE 8-4, QUESTION 3: Four months later, J.G. is admitted to the hospital with atrial fibrillation and is started on amiodarone and apixaban 5 mg twice daily (bid). What medication modifications should be done to J.G.'s medication regimen at this time?

The addition of amiodarone to her medication regimen necessitates a reduction in her dose of simvastatin to 20 mg daily. This dose is still within moderate-intensity range and is acceptable. The other option would be to switch her to different statin that is either not metabolized by CYP3A4 or metabolized to a lesser extent than simvastatin. Reasonable choices of statins would be pravastatin 40 to 80 mg daily, fluvastatin 40 mg bid or XL 80 mg daily, atorvastatin 10 to 80 mg daily, pitavastatin 2 to 4 mg daily, lovastatin 40 mg daily, and rosuvastatin 5 to 40 mg daily.

CLINICAL PEARLS

Approximately 50% of patients discontinue statin therapy within 6 months of initiation, and only one-third are still adherent after a year. Therefore, it is important to minimize adverse effects and be able to identify if the statin may be the cause. The incidence of statin intolerance is estimated to be 5% to 10% among statin-treated patients. However, in light of the new cholesterol guidelines, 13 million more individuals have become eligible for statin therapy, and the overall prevalence of statin intolerance in the United States is likely to increase. Diagnosing statin intolerance is challenging as no universal definition exists. The NLA has several definitions of statin intolerance, but the one most clinically useful is the inability to tolerate at least two statins. The two statins should be one that was prescribed and taken at the lowest starting dose and another one that was taken at any dose. In addition to the two statins challenge, patients need to have either objectionable symptoms or abnormal laboratory values, which are temporally related to statin therapy and reverse upon statin discontinuation and recur upon reinitiation. The ACC has also developed an application called “ACC Statin Intolerance App” designed to assist providers in making the diagnosis of true statin intolerance. The application provides the clinician with a systematic strategy for evaluation of symptoms, management recommendations, as well as information regarding statin characteristics and drug interactions. This application is available on the web at http://tools.acc.org/StatinIntolerance, via Itunes at https://itunes.apple.com/us/app/statin-intolerance/id985805274?mt=8 or via Google Play at https://play.google.com/store/apps/details?id=org.acc.StatinIntolerance&hl=en.

Routine monitoring of LFTs is no longer recommended during statin treatment. However, patients should be made aware of symptoms that may indicate potential hepatic disease, such as flulike symptoms, fatigue, sluggishness, anorexia, weight loss, right upper quadrant pain, yellowing of eyes, or jaundice.

All patients should have a fasting lipid panel before statin initiation. The 2018 AHA/ACC Multisociety guidelines for monitoring of statin therapy recommend a follow-up lipid panel in 4 to 12 weeks following statin initiation to assess patient adherence and response to therapy and then every 3 to 12 months as clinically indicated.[5]

Coenzyme Q10 is an isoprenoid that plays a unique role in cellular electron transport and energy synthesis. It is essential for the normal functioning of muscles. Statins have been shown to reduce blood levels of coenzyme Q10, but muscle tissue concentrations are unaffected. Evidence of the value of supplementing coenzyme Q10 in patients experiencing statin-induced myopathy has been mainly anecdotal. However, the risk of taking CQ10 is relatively small and may be considered in patients with muscle aches in the absence of symptoms that are concerning for more serious muscle-related disease.

Cholesterol Absorption Inhibitor (Ezetimibe)

MECHANISM OF ACTION

Cholesterol that is ingested in the diet and circulated through the bile from the liver is actively reabsorbed in the intestines. Once transported across the intestinal lumen into the enterocyte, it is combined with TG and apo B-48 to form chylomicron particles that transport the lipids through the lymphatic system to the hepatocyte. The TG and cholesterol can then be packaged into VLDL particles and secreted into the systemic circulation (**Fig. 8-12**).

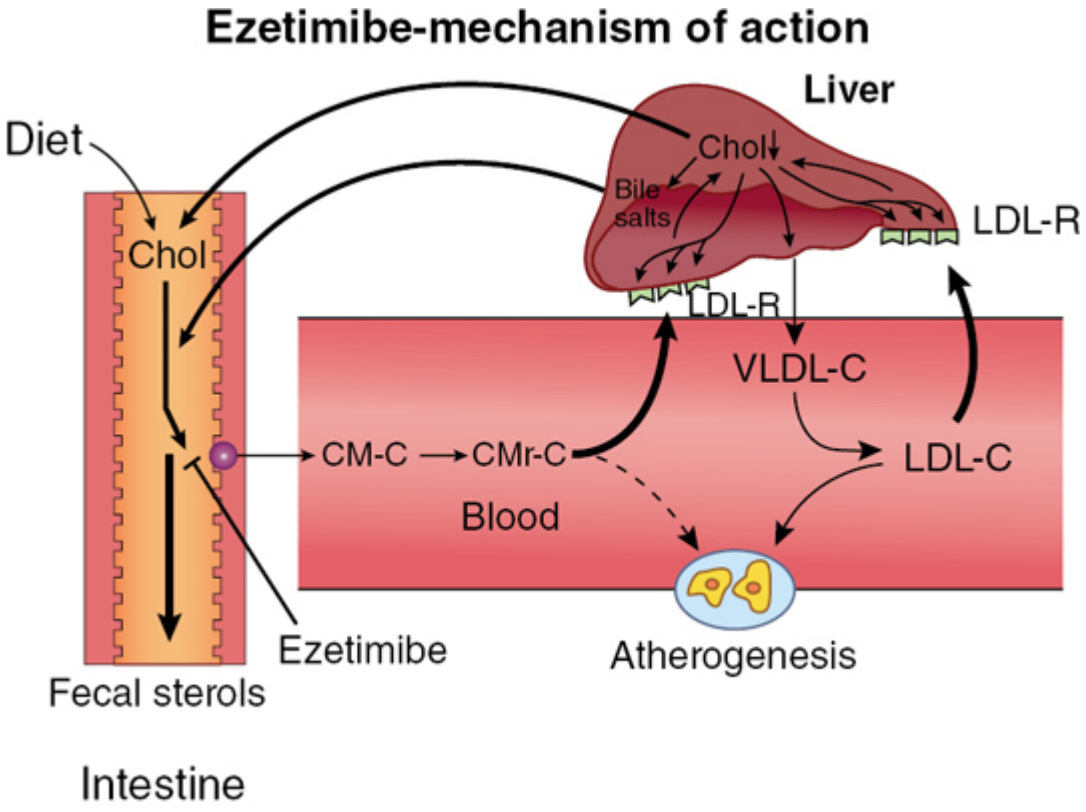

Figure 8-12 Mechanism of action of cholesterol absorption inhibitors. Chol, cholesterol; CM-C, chylomicron cholesterol; CMr-C, chylomicron remnant cholesterol; LDL-C, low-density lipoprotein cholesterol; LDL-R, low-density lipoprotein real; VLDL-C, very low-density lipoprotein cholesterol.

In the small intestine, the Niemann–Pick C1L1 (NPC1L1) transporter is responsible for the uptake of dietary and biliary cholesterol into the small intestine. Ezetimibe interferes with the active absorption of cholesterol and plant sterols from the intestinal lumen into the enterocyte by binding to and inhibiting this transporter. By interfering with the absorption of cholesterol, about 50% less cholesterol is transported from the intestines to the liver by the chylomicrons. This causes an upregulation of hepatic LDL receptors and increased clearance of circulating VLDL and LDL particles. There is also an upregulation in hepatic cholesterol synthesis, which is diverted to the intestines via the bile to replenish the cholesterol available for intestinal absorption processes. The net effect of the inhibition of the NPC1L1 transporter is ~70% increase in GI sterol

excretion, a 50% reduction in hepatic cholesterol concentration, a 90% increase in hepatic cholesterol synthesis, and ~20% increase in LDL-C clearance from the systemic circulation via upregulated LDL receptors.[119,120]

Ezetimibe also inhibits the absorption of sitosterol and other plant sterols from the gut, resulting in about a 40% reduction in blood sitosterol levels. The occurrence of sitosterolemia is rare, but is associated with a high CHD risk. Ezetimibe provides one of the first effective treatments for this rare disorder.

EFFICACY

The ENHANCE (Ezetimibe and Simvastatin in Hypercholesterolemia Enhances Atherosclerosis Regression) trial was a randomized, double-blind, placebo-controlled trial comparing simvastatin 80 mg combined with ezetimibe 10 mg versus simvastatin 80 mg alone administered once daily in 720 patients with HeFH.[121] The primary outcome was the change in mean carotid intima–media thickness (CIMT) after 24 months of treatment. This trial was not statistically powered to determine differences in vascular disease event rates between treatments because of the short study duration and the small number of patients. Mean baseline LDL-C (319 vs 318 mg/dL) and CIMT (0.69 vs 0.70 mm) were similar between the treatment groups. The percent change in LDL-C was significantly ($P < .01$) greater in the simvastatin–ezetimibe group (−55.6%) compared with the simvastatin–placebo group (−39.1%). However, there was no regression in CIMT in either treatment group, and the mean changes in the CIMT were similar between the treatment groups ($P = .29$) after 24 months of treatment. Why was there not a greater change in CIMT in patients randomly assigned to the simvastatin–ezetimibe group compared with the simvastatin–placebo group, given that these patients had a greater reduction in LDL-C? Before randomization, ~80% of the patients in both treatment groups were receiving statin therapy. Moreover, these patients had thinner or near-normal CIMT at baseline when compared with patients with HeFH studied in previously published statin trials[122,123] that did

demonstrate reduced CIMT with high-dose statin therapy. Collectively, this suggests that the patients studied in the ENHANCE trial were aggressively managed for their cholesterol for many years, resulting in the depletion of vascular wall lipids. Therefore, additional aggressive treatment would unlikely result in further regression of an already lipid-depleted carotid vascular wall. In contrast, Avellone et al[124] recently demonstrated that ezetimibe combined with simvastatin caused a significant reduction in CIMT in FH patients with and without a history of MI. These patients had similar mean baseline LDL-C (301 mg/dL) to patients studied in the ENHANCE trial; however, baseline CIMTs in this trial were much larger (1.82 mm without a history of MI and 1.98 mm with a history of MI) than those observed in the ENHANCE trial and were consistent with CIMTs in patients with FH who have not been aggressively treated.

When ezetimibe was combined with simvastatin versus placebo in 1873 patients with mild-to-moderate, asymptomatic aortic stenosis and no previous history of vascular disease, diabetes mellitus, or any other indications for cholesterol-lowering therapy, significantly fewer patients treated with simvastatin–ezetimibe (15.7%) had ischemic CV events compared with the placebo group (20.1%), mainly related to a reduction in coronary artery bypass grafting (P = .02).[125]

The incremental benefits of adding ezetimibe to statin therapy were evaluated in the IMProved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE IT).[126] This was a multicenter, randomized, double-blinded trial involving 18,144 patients that sought to determine the clinical benefit and safety of combination therapy with ezetimibe and simvastatin compared to simvastatin monotherapy in high-risk patients presenting with ACS. This was the first large trial to evaluate the clinical efficacy of adding a nonstatin (ezetimibe 10 mg/day + simvastatin 40 mg/day) to statin (simvastatin 40 mg/day) monotherapy. The primary end point was CV death, nonfatal MI, rehospitalization for UA, coronary revascularization ≥30 days following randomization, or stroke. Over a median follow-up of 57 months, the addition of ezetimibe to simvastatin 40 mg reduced the primary end point by 6.4% when compared with patients who received simvastatin alone (P = .016). The absolute reduction in risk

over 7 years was 2.0%. The reduction in the primary end point was largely driven by a statistically significant reduction in the risk of MI and ischemic stroke. Overall, there was a significant 10% reduction in the risk of CV death, nonfatal MI, or nonfatal stroke. However, there was no difference in all-cause mortality between the two treatment groups. The average LDL-C during the study was 53.7 mg/dL in the simvastatin–ezetimibe group, compared to 69.5 mg/dL in the simvastatin monotherapy group ($P < .001$). The results of this study support the "lower-is-better" premise for LDL-C.[126]

PHARMACOKINETICS/PHARMACODYNAMICS

Ezetimibe is a prodrug that is rapidly conjugated to an active phenolic glucuronide (ezetimibe-glucuronide).[120] The drug is primarily metabolized in the small intestine via glucuronide conjugation with subsequent renal and biliary excretion. The elimination half-life is ~22 hours. Absorption is not affected by food, and ezetimibe may be administered at any time of day without regard to meals. There are no dose adjustments necessary for patients with renal impairment or with mild hepatic insufficiency.

ADVERSE EFFECTS

Ezetimibe is generally well tolerated with minimal adverse effects. The adverse effects that are the most reported include diarrhea, arthralgias, cough, fatigue, abdominal pain, and back pain. However, the incidence is no more frequent with ezetimibe than with placebo. Elevations in serum transaminases have also been reported. When used as monotherapy, the incidence of consecutive elevations (three times or lower the ULN) in serum transaminases is similar between ezetimibe (0.5%) and placebo (0.3%); however, when combined with a statin, the incidence of consecutive elevations in serum transaminases is 1.3% and only 0.4% in patients taking a statin alone. These elevations are usually transient and return to baseline after discontinuation. Although very rare, cases of myopathy and rhabdomyolysis have been reported with ezetimibe monotherapy.

PLACE IN THERAPY

Ezetimibe may be used either alone or in combination with a statin or fenofibrate along with diet for the management of dyslipidemia, specifically to lower LDL-C. Ezetimibe reduces LDL-C by 18% to 22%, but has little effect on TG or HDL-C.[127] In combination with a statin, it demonstrates an additive effect, enhancing LDL-C lowering by an additional 10% to 20%. In fact, when added to a low dose of a statin, the net LDL-C reduction can be similar to the lowering achieved with the maximal dose of the statin.[128] When added to the maximal dose of a statin, it causes further LDL-C reduction, an effect important in patients with very high LDL-C levels requiring substantial reduction to achieve treatment goals.

DRUG INTERACTIONS

Ezetimibe has been evaluated in combination with several other medications. When combined with statins or fenofibrate, there is minimal impact on either drug in terms of an alteration in metabolism and increased bioavailability that requires any additional intervention.[120] Postmarketing data have shown that there are some elevations in the international normalized ratio (INR) when ezetimibe is added to warfarin. The exact mechanism of this interaction is not fully understood, and no specific dose adjustments are necessary for either medication. However, when ezetimibe is initiated in a patient on warfarin, closer monitoring of the INR may be warranted. Cyclosporine in combination with ezetimibe results in increased exposure of both medications. When used in combination, serum concentrations of cyclosporine should be closely monitored and adjusted as clinically indicated. In addition, the recommended initial dose of ezetimibe when used in combination with cyclosporine is 5 mg daily.

When cholestyramine or colestipol is in combination with ezetimibe, there is an 80% reduction in the area under the curve (AUC) of ezetimibe. Therefore, when these combinations are used, ezetimibe should be administered at least 2 hours prior or 4 ounces following the administration of cholestyramine or colestipol.[120] The

absorption of ezetimibe is not affected by colesevelam, and this combination may be preferred.

CLINICAL PEARLS

Adding ezetimibe to a statin results in greater LDL-C reduction than increasing the dose of the statin. Doubling the dose of any statin provides only an additional 6% reduction in LDL-C. The addition of ezetimibe to statin therapy results in ~18% additional reduction in LDL-C. However, maximally tolerated statin therapy is always recommended before consideration of the addition of nonstatin therapy.

Owing to a risk of increased hepatic serum transaminases, these laboratory values should be measured before the addition of ezetimibe to statin therapy and again following 6 weeks of combination therapy.

Ezetimibe monotherapy or combination therapy with statin should be avoided in patients with active liver disease or persistent elevations in serum transaminases that are otherwise unexplained.

Niacin

On the basis of currently available evidence of nonefficacy and potential harms, there are no clear indications for the routine use of niacin preparations, and niacin is, therefore, not considered in this discussion.

CASE 8-5

QUESTION 1: R.P. is a 62-year-old male, with history of CHD (bypass 2 years ago), diabetes, and end-stage renal disease (ESRD) who is on hemodialysis Monday, Wednesday, and Friday. He is on lisinopril 10 mg daily, atorvastatin 40 mg daily, aspirin 81, metoprolol succinate 50 mg daily, insulin, and calcium acetate 667 mg three times daily. His BP is 136/82 mm Hg; HgA_{1c} 11.6%; weight 291.01 pounds (132 kg); height 70 inches (177.80 cm); fasting lipid panel TC = 250 mg/dL, HDL-C = 30 mg/dL, TG = 450 mg/dL.

What would be the most appropriate treatment for R.P. and his dyslipidemia?

While R.P. does have elevated TGs, per the Endocrinology and AHA guidelines, pharmacologic therapy is not indicated at this time. The most important intervention for R.P. is lifestyle modifications. Controlling his diabetes and losing weight can successfully lower his TGs as much if not more than pharmacologic therapy.

Case 8-5, Question 2: If pharmacologic therapy were initiated on R.P. for his hypertriglyceridemia, which agent(s) would be the most appropriate?

All fibric acid derivatives undergo renal elimination, and none of these agents are approved for patients on hemodialysis and are, therefore, not a good option in R.P. ω-3 Fatty acids would be the best option to use in combination with atorvastatin that he is already taking.

Fibric Acid Derivatives

MECHANISM OF ACTION

Fibrates activate peroxisome proliferator-activated receptors α (PPARα), causing most of the beneficial effects on blood lipids.[129] PPARα are located in the nucleus of cells and are ligand-dependent transcription factors that regulate target gene expression. Stimulation of PPARα suppresses the gene responsible for the synthesis of apo C-III and stimulates the gene responsible for LDL receptor synthesis.[129,130] As a result, lipolysis of TGs from VLDL particles and the removal of these particles via hepatic LDL receptors are enhanced. Stimulation of PPARα also increases fatty acid oxidation, reducing the synthesis of TGs in the liver, reducing the TG content of secreted VLDL particles.[130] Stimulation of PPARα may increase the synthesis of apo A-I, the critical building block of nascent HDL, thereby enhancing reverse cholesterol transport. Research also suggests that fibrates stimulate the expression of ABCA-1 transporters in macrophage cells, which are responsible for bringing cholesterol from within the cell to the cell surface, where it can be

taken up by nascent HDL particles and removed from the cell[129] (**Fig. 8-13**).

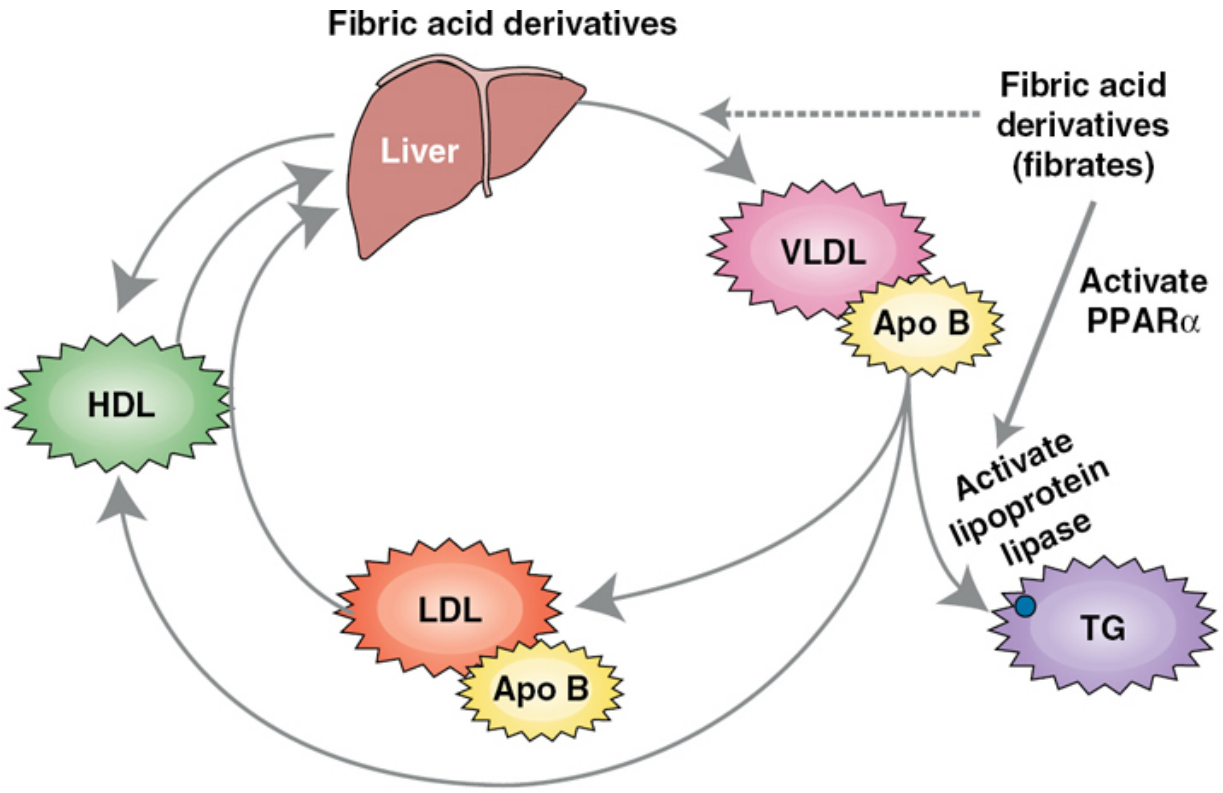

Figure 8-13 Mechanism of action of fibric acid derivatives. apo B, apolipoprotein B; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PPARα, peroxisome proliferator-activated receptor α; TG, triglycerides.

EFFICACY

The results of three major primary prevention trials have raised questions about the safety of fibrates. In the World Health Organization trial, clofibrate reduced nonfatal MI by 25%, but caused an increase in total mortality.[131,132] As a result, its use has declined markedly in the United States. Some of these deaths may have been related to gallstone disease.[131] In the Helsinki Heart Study (HHS), gemfibrozil reduced fatal and nonfatal MI by 37%, but was associated with a slight increase in non-CHD mortality such that there was no net reduction in total mortality.[133] Follow-up evaluations of therapies without gemfibrozil were associated with continued

event reduction. In the Veterans Affairs High-Density Lipoprotein Intervention (VA-HIT) trial, there was a significant 22% relative risk reduction in death from CHD with gemfibrozil ($P < .006$). There was also a 24% reduction in the combined end point of death from coronary revascularization, hospitalization due to angina, nonfatal MI, and stroke ($P < .001$). However, there was no significant effect on mortality.[134] In the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, fenofibrate did not significantly reduce CHD deaths and nonfatal MI compared with placebo. In addition, more patients receiving fenofibrate had pancreatitis or a pulmonary embolism compared with those given placebo.[135] Fenofibrate was also evaluated versus placebo in 418 patients with diabetes and at least one visible lesion on angiographic evaluation in the Diabetes Atherosclerosis Intervention Study (DAIS) trial.[136] The trial was not powered to examine clinical end points, but fewer events, including deaths, occurred in the fenofibrate group. In summary, the clinical trial evidence for CV benefit of the fibric acid derivatives is not as robust as for the statins. The data supporting the use of gemfibrozil in the primary and secondary prevention setting have been established. In contrast, clear improvements in CHD-related outcomes are still lacking for fenofibrate. Thus, these data support the use of fibric acid derivatives as second-line agents, with the exception of use in patients with severe hypertriglyceridemia. More recently, the incremental benefits of adding fenofibrate to background simvastatin therapy on CHD events in patients with diabetes were reported. Only patients with the highest tertile (≥204 mg/dL) of TGs and the lowest tertile (≤34 mg/dL) of HDL-C showed a benefit when fenofibrate was added to statin therapy. Overall, there was an insignificant 8% reduction in the composite CV end point, and fenofibrate appeared to be harmful in females compared with males.[137]

PHARMACOKINETICS/PHARMACODYNAMICS

Fenofibrate and fenofibric acids are well absorbed from the GI tract.[138–145] Fenofibrate is primarily metabolized by conjugation with

peak plasma concentrations within 6 to 8 hours after administration. It is highly bound to plasma proteins, with an elimination half-life of 20 hours. The primary route of excretion is via the urine in the form of metabolites.

On the other hand, gemfibrozil is completely absorbed following administration and reaches peak plasma concentrations within 1 to 2 hours.[146] The rate and extent of absorption is optimal when taken 30 minutes before meals as food can result in a 14% to 44% reduction in the AUC. It is highly bound to plasma proteins, with an elimination half-life of 1.5 hours. It undergoes extensive hepatic metabolism via oxidation of the ring methyl group to form carboxyl and hydroxymethyl metabolites. Gemfibrozil relies significantly on renal excretion, with ~70% being eliminated by the kidneys as a glucuronide conjugate.[146]

Dosing of fibric acid derivatives in patients with renal insufficiency is outlined in **Table 8-9**.

Table 8-9
Dosing of Fibric Acid and Fenofibric Acid Derivatives in Renal Insufficiency

Medication	Usual Dose	Creatinine Clearance 30–59 mL/min	Creatinine Clearance 31–80 mL/min	Creatinine Clearance 30 mL/min or Hemodialysis
Gemfibrozil	600 mg twice daily		No specific recommendations	Not recommended
Fenofibrate (Fenoglide®)	40–120 mg daily		Start at lowest dose of 40 mg daily	Contraindicated
Fenofibrate (Tricor®)	48–145 mg daily	Start at lowest dose of 48 mg		Contraindicated
Fenofibrate (Fibricor®)	35–105 mg daily		Start at lowest dose of 35 mg	Contraindicated
Fenofibrate (Liofen®)[a]	50–150 mg daily		Start at lowest dose of 50 mg daily	Contraindicated
Fenofibrate (Antara®)	43–130 mg daily		Start at lowest dose of 43 mg daily	Contraindicated
Fenofibrate (Lofibra® tablets)	54–160 mg daily		Start at lowest dose of 54 mg	Contraindicated
Fenofibrate (Lofibra® micronized)	67–200 mg daily		Start at lowest dose of 67 mg	Contraindicated
Fenofibrate (Triglide®)	160 mg daily		Avoid use	Contraindicated
Fenofibrate (Trilipix®)	45–135 mg daily	Start at lowest dose of 45 mg		Contraindicated

[a]CrCl is 30–89 mL/min.

ADVERSE EFFECTS

Gemfibrozil, fenofibric acid, and fenofibrate are usually well tolerated. The most common adverse effects associated with fibric acid derivatives include nausea, vomiting, dyspepsia, diarrhea, abdominal pain, flatulence, and constipation. Gemfibrozil causes mild GI symptoms (nausea, dyspepsia, abdominal pain) in about one-third of patients. Fenofibrate causes a rash in 2% to 4% of patients. Fibrate therapy can also cause muscle side effects, including myositis and rhabdomyolysis.[138–143] Most cases of muscle toxicity have been reported with gemfibrozil, especially when it is used in combination with a statin. Recent studies reveal that the area under the blood concentration curve of most statins is increased twofold to fourfold when given concurrently with gemfibrozil. These effects have not been observed with fenofibrate. The mechanism causing this interaction appears to be related to inhibition of glucuronidation by gemfibrozil, which is a metabolic pathway for statins, thereby reducing clearance of statins from the systemic circulation.[147]

Fibric acid derivatives have also been associated with abnormalities in LFTs, including bilirubin and alkaline phosphatase.[138–146] However, these elevations are often not worrisome and usually return to baseline levels upon discontinuation. Fenofibrate has been shown to cause a reversible increase in serum creatinine.[138–145] Although also observed with gemfibrozil, the incidence is lower. Despite this increase, there does not appear to be a resultant decrease in GFR and the mechanism for this effect has not been clearly defined. Gemfibrozil also increases biliary secretion of cholesterol, which increases the lithogenicity of bile and results in the development of cholesterol gallstones. Presumably, the same effect occurs with all fibrates.

PLACE IN THERAPY

Gemfibrozil, fenofibric acid, and fenofibrate are all indicated for the reduction of TG levels in patients with hypertriglyceridemia.[138–146] The 2018 AHA/ACC Multisociety guidelines define severe hypertriglyceridemia at a TG level ≥500 mg/dL.[5] The guidelines state

that to prevent acute pancreatitis, it is reasonable to reduce TGs whenever levels exceed 500 mg/dL by addressing and eliminating the secondary causes, implementing a very low-fat diet, and adding fibrates or ω-3 fatty acids. If a fibrate is necessary in a patient being treated with a statin, it is safer to use fenofibrate than gemfibrozil because of the lower risk of severe myopathy. Similarly, in patients with familial dysbetalipoproteinemia, fibric acid derivatives are highly effective and are considered the drugs of choice. Fibrates also have a place in the management of combined or mixed hyperlipidemia. Support for this comes primarily from the results of the HHS and the VA-HIT trials, in which gemfibrozil combined with diet therapy was associated with a reduction in CHD deaths and nonfatal MI.[133,134] These positive outcomes are attributed to significant reductions in serum TGs (and, therefore, a reduction in TG-rich VLDL remnants and in small, dense LDL) and an increase in HDL-C. Persons most likely to benefit are those with diabetes or the lipid triad found in patients with the metabolic syndrome.

DRUG INTERACTIONS

Drug interactions associated with fibric acid derivatives are fairly well known, and several of these drug interactions can be managed by careful monitoring. The most clinically significant interactions occur with statins, warfarin, repaglinide, cholestyramine, and colestipol. The combination of statins and gemfibrozil increases systemic concentrations of the statin and raises the risk for the development of myopathy and rhabdomyolysis. As previously mentioned, data suggest that there is less risk of a significant drug interaction with fenofibrate and subsequently a lower risk of myopathy and rhabdomyolysis. The combination of gemfibrozil should be avoided with lovastatin, pravastatin, and simvastatin. The maximum dose of rosuvastatin should be 10 mg daily when combined with gemfibrozil. Although gemfibrozil does interact with atorvastatin and pitavastatin, the increase in statin concentrations is minor, and the combination may be utilized if clinically indicated. However, there are no data demonstrating that adding a fibrate to a statin will reduce CHD risk.

The coadministration of gemfibrozil with ezetimibe may cause increased cholesterol excretion into the bile, increasing the risk of cholelithiasis.[120,146] This does not appear to be a concern with fenofibrate and ezetimibe combination.

CASE 8-6

QUESTION 1: J.S. is a 46-year-old male with a history of hypertension and diabetes. He presented to his primary care physician with abdominal pain that began 2 days ago and radiated to his mid-back. He also has some vomiting. All of his vital signs were within normal limits. On physical examination, he has tenderness over his abdominal area that is more severe in the epigastric region.

Pertinent laboratory values include an HgA_{1c} of 13.6% and the following cholesterol panel: TC 467 mg/dL, HDL-C 30 mg/dL, TG 1872 mg/dL, LDL-C was unable to be calculated, amylase 325 U/L, and lipase 3265 U/L.

Following acute management of his pancreatitis, what would be the most appropriate treatment for J.S.?

This is an individual who is at high risk for pancreatitis as well as ASCVD. His risk score using the new risk calculator based on recent guidelines reveals a 10-year risk of about 18.6% and a statin is indicated. In addition, the endocrinology guidelines define a TG level of ≥1000 mg/dL as severe and the AHA/ACC Multisociety guidelines define a level ≥500 mg/dL as very high and that pharmacologic therapy should be initiated. J.S. should be initiated on a statin and a fibric acid derivative, or two different agents to lower TGs first such as ω-3 fatty acids plus fibric acid derivative to get TGs down and then consider the addition of a statin.

CASE 8-6, QUESTION 2: What are some considerations when using fibric acid derivatives in combination with statins?

The risk of adverse effects of statin–fibrate combination therapy is dependent on pharmacokinetic interactions that alter statin metabolism and clearance. One of the most significant drug interactions with statins and a fibric acid derivative is the combination of a statin with gemfibrozil. Gemfibrozil inhibits glucuronidation,

which is an elimination pathway of all statins, with the exception of fluvastatin. This interaction can lead to increased concentrations of these statins, increasing the risk of toxicity. In contrast, fenofibrate appears to have a minimal effect and is considered a safer alternative. The use of gemfibrozil with simvastatin, pravastatin, or lovastatin should be avoided. The combination of gemfibrozil with atorvastatin, pitavastatin, and rosuvastatin may be considered if fenofibrate is not an option.[118] However, lower doses of statins should be used to minimize adverse effects. Labeling for rosuvastatin suggests limiting the daily dose of rosuvastatin to 10 mg daily when used with gemfibrozil.

CLINICAL PEARLS

Many different formulations of fenofibrate are available, with the dose ranging from 130 to 200 mg. All products are dosed once daily. For the treatment of hypertriglyceridemia, the initial dose may be at the lower end of the dosing range. If the initial dose chosen is lower than the maximum dose, it should be titrated upward at 4- to 8-week intervals based on patient response up to the maximum dose.

Obtain a baseline serum creatinine before the initiation of therapy.

Gemfibrozil is preferred in renal insufficiency.

Consider discontinuation of fibric acid derivative or a dose reduction in the setting of otherwise unexplained increases in serum creatinine.

Fenofibrate is the preferred agent to use when combination with a statin is warranted.

Obtain a baseline CK before adding a fibrate to statin therapy and in those patients at high risk.

Patients who receive any fibric acid derivative therapy either alone or in combination with a statin should be monitored for symptoms of muscle soreness and pain. If these symptoms emerge, a CK level should be obtained. CK level ≥10 times the ULN in combination with muscle symptoms supports a diagnosis of myositis. If other possible causes are not apparent, such as increased physical exercise or a

recent trauma or fall, the presence of myositis is an indication to withdraw fibrate therapy.

v-3 Fatty Acids

MECHANISM OF ACTION

The exact mechanism by which the ω-3 fatty acids, docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), lower TGs is not fully understood. There are currently three prescription fish oil formulations available: combined EPA and DHA in ethyl ester form, EPA ethyl ester only, and EPA and DHA in carboxylic acid form.[148–150] The ethyl ester formulation may possibly work through inhibition of acyl-CoA:1,2-diacylglycerol acyltransferase and increased peroxisomal B oxidation. However, DHA and EPA inhibit the esterification of other fatty acids, and TG lowering may be due to a reduction in hepatic TG synthesis.[148] The active metabolite of icosapent ethyl ester reduces hepatic VLDL-TG synthesis and/or secretion and increases TG clearance from circulating VLDL particles.[149] The potential mechanisms of action for the carboxylic acid formulation include inhibition of acyl-CoA:1,2-diacylglycerol acyltransferase, increased mitochondrial and peroxisomal oxidation in the liver, decreased lipogenesis in the liver, and increased plasma LPL activity. This agent may reduce the synthesis of TGs in the liver.[149]

EFFICACY

Consumption of foods rich in ω-3 fatty acids (eg, fish) several times a week has been associated with a reduced risk of heart disease and is recommended as part of a low-fat diet. Supplements of fish oils demonstrated a reduction in CHD in patients with a recent MI[151] as well as patients taking statins.[152] Recently, however, other trials have failed to demonstrate the benefits of ω-3 fatty acids in addition to standard CV drugs, such as statins, angiotensin-converting enzyme (ACE) inhibitors, β-blockers, and antiplatelet agents.[153] Commercial sources of fish oils vary in their content. The ω-3 fatty

acids used in the GISSI study, which demonstrated a CHD risk reduction, contained 850 mg of combined EPA and DHA. Recently, two trials, the Reduction of Cardiovascular Events with EPA-Intervention trial (REDUCE-IT) and Outcome Study to Assess Statin Residual Risk Reduction with Epanova in Hypertriglyceridemia (STRENGTH), evaluated CV outcomes in patients with CHD or at high risk for CHD (REDUCE-IT) or high risk for CHD (STRENGTH) already taking statin therapy.[154,155]

The STRENGTH trial was an international, randomized, double-blind, placebo-controlled trial evaluating the effects of ω-3 carboxylic acid preparation on reducing the rate of CV events in high-risk patients with hypertriglyceridemia and low HDL-C levels. Inclusion criteria were a TG level ≥180 to 500 mg/dL and HDL-C <42 mg/dL. Patients were also required to be on background statin therapy for at least 4 weeks and have an LDL-C of <100 mg/dL. However, an LDL-C of >100 mg/dL was allowed if on maximum tolerated statin therapy. Patients either received 4 g daily of ω-3 carboxylic acid or placebo. The primary outcome was time to first event of CV death, MI, stroke, coronary revascularization, or hospitalization for UA. The study was stopped early based on recommendation from an independent data monitoring board because of the low likelihood of the study demonstrating a benefit.[154]

However, results from The Reduction of Cardiovascular Events with Icosapent Ethyl-Intervention Trial (REDUCE-IT) evaluating EPA demonstrated CV benefits.[155] This was a multicenter, randomized, double-blind, placebo-controlled trial comparing icosapent ethyl 2 g bid to placebo in 8179 patients for secondary prevention of CV events. This study included patients established CVD or with diabetes and other risk factors, who had been receiving statin therapy a fasting TG level between 150 and 499 mg/dL and LDL-C 41 to 100 mg/dL. The median follow-up period was 4.9 years. All patients were on background statin therapy. The primary end point was a composite of CV death, nonfatal MI, nonfatal stroke, coronary revascularization, or UA. The results revealed a significant reduction in the occurrence of the primary end point of 17.2% in the icosapent ethyl group compared to 22% in the placebo (hazard ratio [HR] 0.75;

95% confidence interval [CI] 0.68–0.83; *P* < .001). A significant reduction in the rate of additional ischemic events, including CV death, was also observed with icosapent ethyl (4.3%) compared to placebo (5.2%; *P* = .03). However, there was a significantly higher risk of atrial fibrillation or flutter in the icosapent ethyl group compared to placebo (3.1% vs 2.1%; *P* = .004).

PHARMACOKINETICS/PHARMACODYNAMICS

There is limited pharmacokinetic or pharmacodynamic data available for these agents. The combined EPA and DHA ethyl ester formulation (Lovaza®, Omtryg®) is well absorbed following oral administration. The EPA and DHA carboxylic acid preparation (Epanova®) is directly absorbed in the small intestines subsequently entering the systemic circulation mainly via the thoracic duct lymphatic system.[150] Steady-state concentrations of EPA and DHA in plasma are achieved within 2 weeks following repeat daily dosing. The ω-3 fatty acids in carboxylic acid form may be administered without regard to meals. They are mainly oxidized in the liver and do not undergo renal elimination.

Following oral administration, the EPA ethyl ester preparation (Vascepa®) is de-esterified during process, and the active metabolite EPA is absorbed in the small intestine and enters the systemic circulation mainly via the thoracic duct lymphatic system.[149] Peak plasma concentrations of EPA are reached in ~5 hours. No studies on the effect of food on this product have been conducted. However, the recommendation is for it to be taken with or following a meal. The EPA ethyl ester is mainly metabolized by the liver via β-oxidation. This β-oxidation splits the long carbon chain of EPA into acetyl coenzyme A, which is then converted into energy via the Krebs cycle. EPA ethyl ester does not undergo renal elimination.

ADVERSE EFFECTS

The most common adverse effects associated with Lovaza® are eructation, dyspepsia, and taste perversion. In addition to eructation, Epanova® has also been reported to cause diarrhea, nausea, and

abdominal pain. The most common adverse effect reported with Vascepa® is arthralgia.

PLACE IN THERAPY

Fish oils predominantly contain long-chain polyunsaturated (ω-3) fatty acids, EPA and DHA, which lower TG levels significantly (30%–60%) but have variable effects on cholesterol levels. They do not provide clinically significant LDL-C reduction. All of the available prescription products may be used as an adjunct to diet to treat hypertriglyceridemia (≥500 mg/dL). However, based on the results of the REDUCE-IT trial, icosapent ethyl is also indicated as an adjunct to maximally tolerated statin therapy to reduce the risk of MI, stroke, coronary revascularization, and UA requiring hospitalization in adults with elevated TG levels (≥150 mg/dL), AND established CVD, or diabetes mellitus and two or more additional risk factors for CVD. The National Lipid Association Scientific Statement on the use of icosapent ethyl in statin-treated patients with elevated TGs and high or very high ASCVD risk recommends icosapent ethyl for ASCVD risk reduction in high- and very high-risk patients who are either 45 years and older with clinical ASCVD or 50 years and older with type 2 diabetes, fasting TGs 135 to 499 mg/dL and at least one additional risk factor.[156] For patients with type 2 diabetes, icosapent ethyl is recommended only if patients are on maximum tolerated doses of a statin, with or without ezetimibe (NLA). The ADA guideline recommendations are very similar in that icosapent ethyl should be reserved for patients whose TG levels persist between 135 and 499 mg/dL despite statin therapy.[157]

The recommended dose of Lovaza® is 4 g/day in either a single or divided dose. The dose for Vascepa® is 2 g bid with food and for Epanova® is 2 to 4 g daily.

DRUG INTERACTIONS

No significant drug interactions have been reported with any of the prescription products. However, some studies suggest that the use of ω-3 fatty acids may prolong bleeding time. However, there have

been no thorough clinical trials conducted to determine the magnitude of this interaction. Therefore, patients taking these along with other anticoagulants should be evaluated more closely for any signs of increased bleeding.

CLINICAL PEARLS

ω-3 Fatty acid capsules should be swallowed whole. Do not break open, crush, dissolve, or chew.

Administering fish oil before meals may decrease the fishy taste.

EPA has negligible effect on LDL-C. Both EPA and DHA lower TGs, but DHA as well as the combination of EPA/DHA are more effective than EPA-only preparations. DHA-containing preparations may increase LDL-C, mechanism likely due to increase in apo C-III production.

Bile Acid Resins

MECHANISM OF ACTION

Bile acids are secreted into the intestines and are responsible for emulsifying fat and lipid particles in food. Most of the bile acids that are secreted are reabsorbed and returned to the liver by enterohepatic circulation. The BASs are anion exchange resins that bind bile acids in the intestinal lumen and cause them to be eliminated in the stool.[158–161] By disrupting the normal enterohepatic recirculation of bile acids from the intestinal lumen to the liver, the liver is stimulated to convert hepatocellular cholesterol into bile acids. This results in a reduction in the concentration of cholesterol in the hepatocyte, prompting upregulation of LDL receptor synthesis. Finally, circulating LDL-C levels are lowered by binding to the newly formed LDL receptors on the liver surface (**Fig. 8-14**).

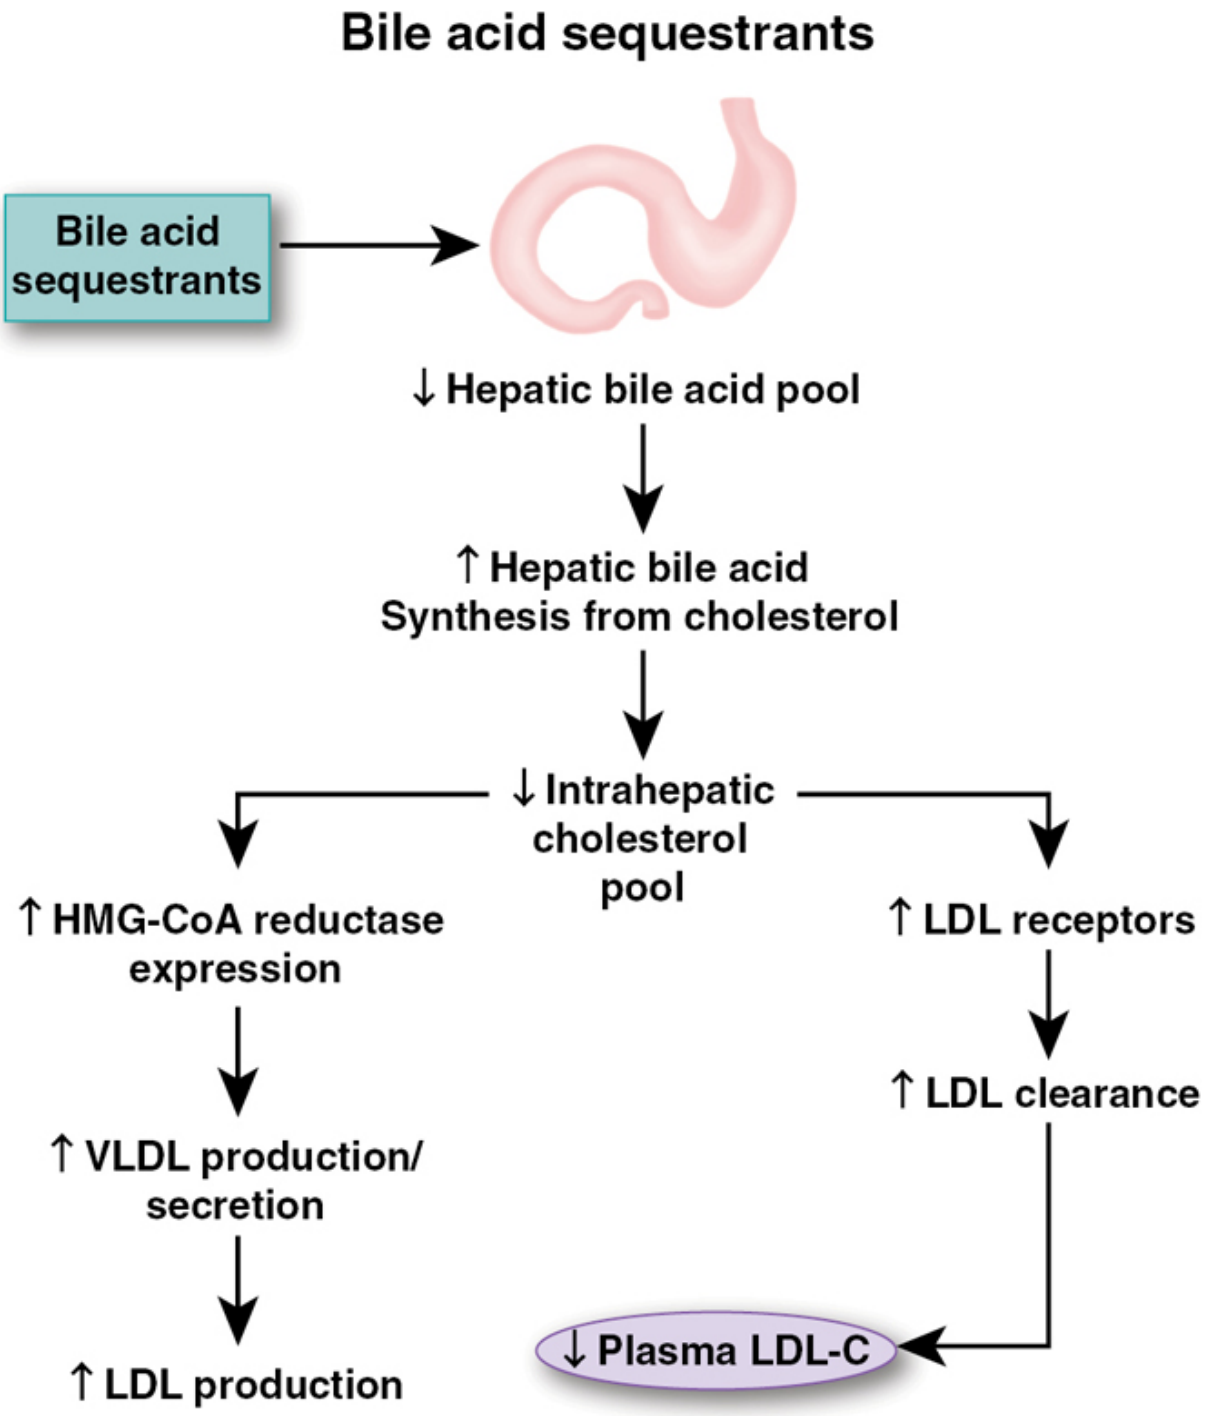

Figure 8-14 Mechanism of action of bile acid sequestrants. HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein; LDL-C, low-density lipoprotein cholesterol; VLDL, very low-density lipoprotein.

EFFICACY

The BAS agents have demonstrated the ability to reduce CHD events in the Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CCPT).[162] This was a randomized, multicenter trial evaluating the efficacy of cholesterol lowering in reducing CAD risk in 3806 males with primary hypercholesterolemia. In conjunction with diet, patients were randomized to cholestyramine 24 g/day or placebo. The mean follow-up was 7.4 years. The primary end point of combined CAD death and nonfatal MI was reduced by 19% in the patients treated with cholestyramine compared to placebo-treated patients ($P < .05$). This study also supports the "lower-is-better" hypothesis of LDL-C.[162,163] These agents reduce LDL-C between 12% and 27% and TC by 8% and 27%. HDL-C is increased minimally by around 3% to 10%. All of the BAS also may raise TG levels by 3% to 10% or more, especially in patients with high TG levels.

PHARMACOKINETICS/PHARMACODYNAMICS

Colesevelam is a nonabsorbable polymeric compound that binds to bile acids more strongly and more specifically than the other available BAS.[161] Colestipol and cholestyramine are nonabsorbable hydrophilic basic anion exchange resins. All of these agents are insoluble in water.[159,160]

ADVERSE EFFECTS

The most common adverse effect associated with these agents is constipation. Additional adverse effects include abdominal bloating, epigastric fullness, nausea, vomiting, steatorrhea, and flatulence.[159–162] The incidence of these GI symptoms is less with colesevelam.

PLACE IN THERAPY

BAS are indicated as an adjunct to diet and exercise to lower LDL-C. These agents may be used either alone or in combination with statins. The BAS have appealed in the management of hypercholesterolemia because they have a strong safety record and they effectively lower LDL-C. They are not absorbed from the GI

tract and thus lack systemic toxicity. Older BAS (cholestyramine, colestipol) are not well tolerated because of numerous GI side effects and the unpleasant granular texture of the powder. Therefore, colesevelam is currently the preferred agent. Colesevelam is indicated as either monotherapy or in combination with a statin to reduce LDL-C levels in boys and postmenarchal girls, ages 10 to 17 years, with HeFH. Therapy may be initiated following adequate trial of diet if LDL-C remains ≥190 mg/dL or LDL-C remains ≥160 mg/dL and there is a positive family history of premature ASCVD or two or more other CVD risk factors. Colesevelam is also approved by the FDA for use in type 2 diabetes to improve glycemic control.[161]

DRUG INTERACTIONS

Reduction in the absorption of fat-soluble vitamins and folic acid has been reported with high dosages of BAS, but this is rarely a problem in otherwise healthy patients consuming a nutritionally balanced diet. Cholestyramine and colestipol may reduce or delay the absorption of medications when coadministered.[159–161] This can be minimized by administering other medications 1 hour before or 4 hours after the resin dose. The resins may also reduce the absorption of warfarin, levothyroxine, thiazide diuretics, β-blockers, and, presumably, other anionic drugs. Colesevelam has been shown to reduce the levels of glimepiride, glipizide, glyburide, levothyroxine, cyclosporine, olmesartan, and oral contraceptives containing ethinylestradiol and norethindrone. To avoid these interactions, these agents should be administered 4 hours before colesevelam. Colesevelam has also been shown to increase metformin levels, and patients should be monitored for clinical response. Postmarketing reports have also shown an interaction with phenytoin. As with the other drug interactions, phenytoin should be administered 4 hours before colesevelam.

CLINICAL PEARLS

The use of BAS should be avoided in patients with complete biliary obstruction.

BAS agents are contraindicated if TGs are >500 mg/dL and in patients with a history of hypertriglyceridemia-induced pancreatitis.

Colesevelam for oral suspension should be mixed with 4 to 8 ounces of water, fruit juice, or diet soft drinks.

These agents should be initiated only when TG levels are <300 mg/dL.

Microsomal Triglyceride Protein Inhibitors (Lomitapide)

MECHANISM OF ACTION

Lomitapide is the first in a new class of antihyperlipidemic agents to improve lipoprotein profiles in patients with HoFH. MTP resides in the lumen of the endoplasmic reticulum. Inhibiting MTP production prevents the assembly of apo B–containing lipoproteins in enterocytes and hepatocytes. This subsequently inhibits the production and subsequent secretion of chylomicrons and VLDL, and subsequent production of LDL-C.[164]

EFFICACY

There is one pivotal phase 3 study that ultimately led to the approval of lomitapide. This was a multinational, single-arm, open-label, 78-week trial in 29 patients with HoFH.[165] Following a 6-week run in phase, patients were initiated on lomitapide 5 mg daily and titrated to doses of 10, 20, 40 mg, up to 60 mg, based on tolerability and liver enzymes levels.[165] Patients were also instructed to follow a low-fat diet (<20% of calories from fat) as well as to take dietary supplements to replace fat-soluble nutrients.

Initial efficacy was assessed after 26 weeks and then patients were continued on the study medication for an additional 52 weeks to assess for long-term safety. The primary end point was change in LDL-C from baseline at 26 weeks. The results showed that lomitapide, when added to the existing lipid-lowering therapy, significantly reduced LDL-C by an average of 40% from baseline at week 26.[165]

PHARMACOKINETICS/PHARMACODYNAMICS

Lomitapide undergoes extensive hepatic metabolism. Metabolic pathways include oxidative-*N*-dealkylation, glucuronide conjugation, oxidation, and piperidine ring opening. The CYP3A4 isoenzyme metabolizes lomitapide to its major metabolites. Lomitapide is highly bound to plasma proteins (99.8%) and has a mean terminal elimination half-life of 39.7 hours. Approximately 59.5% and 33.4% of the dose are excreted in the urine and feces, respectively.[164]

PLACE IN THERAPY

Lomitapide is approved as an adjunct to a low-fat diet and other lipid-lowering therapies, including LDL apheresis, to reduce LDL-C, TC, apo B, and non–HDL-C in patients with HoFH. Owing to the concern for liver injury, the drug is only available through a Risk Evaluation and Mitigation Strategies (REMS) program. Given the risk of adverse effects, unknown effects on CV morbidity and mortality and the absence of data in the non-HoFH population, lomitapide treatment should be restricted to patients with HoFH.

ADVERSE EFFECTS

The primary adverse effects associated with lomitapide include GI symptoms, elevated transaminases, and hepatic steatosis. The most common GI symptom report was diarrhea, which occurred in 79% of patients, followed by nausea (65%), dyspepsia (38%), and vomiting (34%). Additional GI symptoms that have been reported include abdominal pain and discomfort, constipation, and flatulence. To minimize the risk of these adverse effects, patients should adhere to a diet that is low in fat (<20% of daily energy). Elevations in hepatic transaminases occurred in 34% of patients. The degree of elevation ranged from an ALT or AST of three times or above the ULN to five times the ULN. However, no patients in the clinical trial had to discontinue therapy because of elevated transaminases.

DRUG INTERACTIONS

The use of lomitapide in combination with strong inhibitors of CYP3A4 (boceprevir, clarithromycin, conivaptan, indinavir, itraconazole, ketoconazole, lopinavir/ritonavir, mibefradil, nefazodone, nelfinavir, posaconazole, ritonavir, saquinavir, telaprevir, voriconazole, telithromycin), moderate inhibitors of CYP3A4 (amprenavir, aprepitant, erythromycin, fluconazole, fosamprenavir, imatinib, verapamil, crizotinib, atazanavir, diltiazem, darunavir/ritonavir) as well as grapefruit juice is contraindicated. Strong CYP3A4 inhibitors in combination with lomitapide can result in ~27-fold increase in exposure of lomitapide. Moderate CYP3A4 inhibitors in combination with lomitapide have not been fully evaluated but are expected to increase lomitapide levels. Even weak CYP3A4 inhibitors can increase lomitapide exposure by approximately twofold. When lomitapide is used in combination with warfarin, the INR may increase by as much as 22%. Lomitapide in combination with simvastatin leads to doubling of simvastatin exposure. When used in combination with statin therapy, the dose of statin should be reduced by 50% and the dose of simvastatin should be limited to 20 mg daily. A dose of simvastatin of 40 mg daily may be used if patients have previously tolerated simvastatin for at least a year at a dose of 80 mg daily. Although specific drug interactions between lomitapide and lovastatin have not been studied, given that the metabolizing enzymes and transporters responsible for the disposition of these two agents are similar, a reduced dose of lovastatin should be considered. Lomitapide is also an inhibitor of P-glycoprotein (P-gp). The use of lomitapide in combination with P-gp substrates (aliskiren, fexofenadine, topotecan, sitagliptin, saxagliptin, imatinib, maraviroc, digoxin, dabigatran, ambrisentan, colchicine, everolimus, lapatinib, nilotinib, posaconazole, sirolimus, talinolol, tolvaptan) may lead to increased absorption of these agents, and dose reduction should be considered. Although not tested, it is recommended that BAS be administered at least 4 hours apart from lomitapide. This is to avoid potential interference with absorption of lomitapide.[162]

CLINICAL PEARLS

The initial dose of lomitapide is 5 mg once daily with a full glass of water, and at least 2 hours following the evening meal.

Patients should adhere to a low-fat diet consisting of <20% of their dietary intake when prescribed lomitapide.

Patients should also consume supplements (provided by pharmacy with lomitapide prescription) that contain vitamin E (400 IU), linoleic acid (200 mg), α-linolenic acid (210 mg), EPA (110 mg), and DHA (80 mg).

The dose of lomitapide can be increased after 2 weeks to 10 mg once daily and then titrated upward as follows: at 6 weeks, increase the dose to 20 mg once daily; at 10 weeks, increase to 40 mg once daily; and after 14 weeks, the dose may be increased to the maximum dose of 60 mg.

The maximum dose in patients with ESRD on hemodialysis or mild hepatic impairment is 40 mg once daily.

The use of lomitapide is contraindicated in patients with active liver disease (unexplained persistent elevations of serum transaminases), moderate-to-severe hepatic impairment, pregnancy, as well in combination with moderate or strong CYP3A4 inhibitors, as outlined earlier.

Patients on warfarin along with lomitapide should have their INR closely monitored and warfarin dosage adjusted as needed.

Obtain ALT, AST, and total bilirubin before initiation of therapy, before each dose increase, or monthly, whichever comes first.

After the first year of therapy, ALT, AST, and total bilirubin should be monitored at least every 3 months and before any dose increase. If the LFTs are greater than three times the ULN and less than five times the ULN, repeat labs in 1 week to confirm the elevation. If the elevation is confirmed, reduce the dose and obtain additional liver-related tests. Repeat labs weekly and discontinue therapy if LFTs increase to greater than five times the ULN and do not decrease to less than three times the ULN within ~4 weeks.

Apo B Antisense Oligonucleotides

MECHANISM OF ACTION

Mipomersen is an antisense oligonucleotide targeted to human messenger ribonucleic acid (mRNA) for apo B-100. Mipomersen is complementary to the coding region of the mRNA for apo B-100 and binds by Watson and Crick (guanine–cytosine and adenine–thymine) base pairing. The hybridization of this agent to the cognate mRNA results in RNase H-mediated degradation of the cognate mRNA, thereby inhibiting translation of the apo B-100 protein. This action leads to reduced apo B synthesis, the structural core for all atherogenic lipids, including LDL-C.[165–168]

EFFICACY

Mipomersen has been evaluated in two phase 3 studies. The first was a randomized, double-blind, placebo-controlled multicenter trial in 58 patients with FH. Patients were included if their LDL-C was ≥140 mg/dL or LDL-C ≥92 mg/dL plus CAD, on maximally tolerated lipid-lowering therapy. Patients were administered subcutaneous (SQ) dose of 200 mg of mipomersen weekly for 26 weeks or placebo.[169] The results showed a 36% reduction in LDL-C versus a 13% increase with placebo ($P < .001$). In addition, apo B and lipoprotein(a) were also significantly reduced ($P < .001$). ALT and AST were increased in 21% and 13% of patients, respectively. Hepatic steatosis was observed, with an incidence of 13%. The second phase III study was also a randomized, double-blind, multicenter study evaluating 158 patients with baseline LDL-C ≥100 mg/dL with or at high risk for CAD and on maximum tolerated lipid-lowering therapy.[170] As with the previous study, mipomersen 200 mg was administered SQ once a week for 26 weeks. The results revealed a 36.9% reduction in LDL-C compared to a 4.5% reduction with placebo ($P < .001$). Apo B was significantly reduced by 38% as was lipoprotein(a) by 24% ($P < .001$). In addition, half of the patients achieved LDL-C levels of <70 mg/dL in the mipomersen group. Elevations in ALTs observed were similar to other studies, and ALT greater than three times the ULN occurred in 10% of patients.

PHARMACOKINETICS/PHARMACODYNAMICS

Mipomersen is administered via SQ injection. The drug has a bioavailability ranging from 54% to 78%. Peak plasma concentrations are generally obtained within 3 to 4 hours. With weekly administration, steady state is reached within ~6 months. It is highly bound to human plasma (≥90%) and has an elimination half-life of 1 to 2 months following SQ administration. Mipomersen is metabolized in tissues by endonucleases to form shorter oligonucleotides that are then substrates for additional metabolism by exonucleases. Mipomersen is not a substrate for the CYP450 enzyme system. Elimination occurs via metabolism in the tissues and urinary excretion.[166]

ADVERSE EFFECTS

The most common adverse effects associated with mipomersen with an incidence of ≥10% include injection site reactions, flulike symptoms, nausea, headache, and elevated hepatic transaminases, specifically ALT. Injection site reactions occur in 84% of patients and consist of pain, tenderness, erythema, pruritus, and local swelling. Flulike symptoms occur in 30% of patients and are usually noticed within 2 days after the injection, including pyrexia, myalgia, chills, arthralgia, fatigue, and malaise. Elevations in hepatic transaminases occurred in ~12% of patients, with 9% having an ALT three times or above the ULN. Hepatic steatosis has also been reported.

PLACE IN THERAPY

Mipomersen is indicated as an adjunct therapy to a low-fat diet and other lipid-lowering agents to reduce LDL-C, apo B, TC, and non-HDL in patients with HoFH.[166] Owing to the concern for hepatotoxicity, mipomersen is also available only through an REMS program. Although mipomersen has only been studied in combination with simvastatin and ezetimibe therapies, its use with other nonstatin lipid-lowering agents as well as in patients undergoing LDL-C apheresis is not recommended. The effect of mipomersen on CV morbidity and mortality is unknown. In addition,

the safety and efficacy of mipomersen has not been established in patients with hypercholesterolemia not secondary to HoFH. Maximum LDL-C reduction is usually seen after ~6 months of therapy.

DRUG INTERACTIONS

Secondary to the unique metabolism of mipomersen, there are no known clinically significant drug interactions. However, caution should be exercised when used with other medications known to have potential for hepatotoxicity (eg, isotretinoin, amiodarone, acetaminophen [>4 g/day for ≥3 days/week]), methotrexate, tetracyclines, and tamoxifen. If used in combination, more frequent monitoring of liver-related tests may be necessary.

CLINICAL PEARLS

Alcohol consumption should be limited to no more than 1 drink/day because it may increase hepatic fat and induce or exacerbate the risk of liver injury.

The recommended dose of mipomersen is 200 mg by SQ injections once a week.

If a dose is missed, the injection should be given at least 3 days from when the next weekly dose is due.

Mipomersen should be stored in the refrigerator but removed from the refrigerator and allowed to reach room temperature for at least 30 minutes before administration.

Injection sites include the abdomen, thigh area, or the outer area of upper arm.

Mipomersen should not be injected into any site that has injury to the skin, such as sunburn, rash, skin infections, inflammation, or active areas of psoriasis, or in areas with tattoos or scars.

A full liver panel to include ALT, AST, total bilirubin, and alkaline phosphatase should be obtained before therapy initiation.

Mipomersen is contraindicated in patients with moderate or severe hepatic impairment or active liver disease.

For the first year, liver-related tests at least an ALT and AST should be checked monthly.

After the first year of therapy, liver tests should be checked at least every 3 months.

Discontinue therapy if persistent or clinically significant elevations occur.

If transaminase elevations are accompanied by clinical symptoms of liver injury, increases in bilirubin by two times or above the ULN, or active liver disease, therapy should be discontinued.

Lipid levels should be monitored at least every 3 months for the first year.

Proprotein Convertase Subtilisin/Kexin Type 9 monoclonal Antibodies (PCSK9 mAb)

MECHANISM OF ACTION

PCSK9 is a member of the proprotein convertase family, which consists of nine members. PCSK9 is thought to play a critical role in modulating the number of LDL receptors on the surface of the hepatocyte and consequently the amount of LDL-C in the plasma. PCKS9 binds irreversibly to LDL receptors on the hepatocyte and is internalized into the liver cells. This prevents the LDL receptor from being recycled back to the cell surface and the LDL-R/PCSK9 complex is degraded along with the LDL-C. Monoclonal antibodies to PCKS9, or PCSK9 inhibitors, neutralize PCSK9 and prevent PCSK9-mediated LDL receptor degradation, allowing more LDL receptors to return back to the cell surface. An increase in the number of LDL receptors leads to enhanced clearance of LDL-C and thus lowers LDL-C levels (**Fig. 8-15**).[171,172]

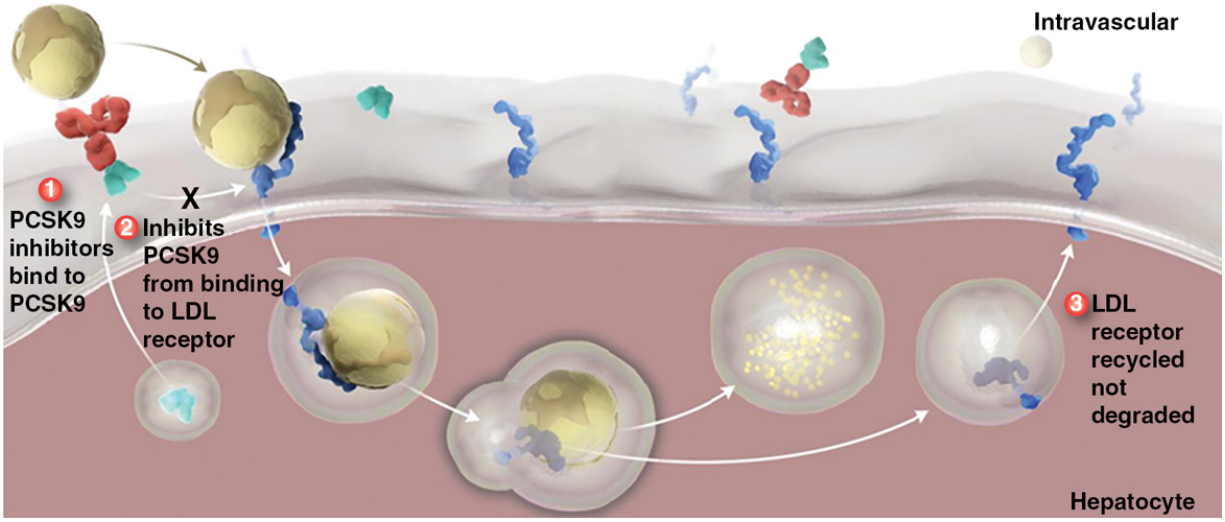

Figure 8-15 Mechanism of action of proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors. 1. PCSK9 inhibitors bind to PCSK9 made in the hepatocyte. 2. By binding to the PCSK9 receptor, PCKS9 inhibitors prevent PCSK9-mediated low-density lipoprotein (LDL) receptor degradation. 3. Secondary to reduce degradation, more LDL receptors are recycled back to the cell surface that subsequently leads to lower LDL-C levels. Used with permission of Amgen.

EFFICACY

These agents have been evaluated in patients with HeFH and HoFH and in patients with ASCVD who have been on maximally tolerated statin doses and require further LDL-C reduction.

The LAPLACE-2 (LDL-C Assessment with PCSK9 Monoclonal Antibody Inhibition Combined with Statin Therapy) trial was a 12-week trial to evaluate the safety and efficacy of evolocumab in 2067 patients with primary hypercholesterolemia and mixed dyslipidemia.[173] The study included 296 patients with clinical ASCVD. Patients were randomized to a specific, open-label regimen of three different statin doses (atorvastatin 80 mg daily, rosuvastatin 40 mg daily, or simvastatin 40 mg daily) and either fixed-dose evolocumab 140 mg every 2 weeks, evolocumab 240 mg once a month, or placebo. The primary end point was change in baseline LDL-C at 12 weeks, with a secondary end point of percent of

patients achieving LDL-C <70 mg/day. The results showed that in patients already on either moderate- or high-intensity statin therapy and clinical ASCVD, evolocumab demonstrated an additional mean reduction in LDL-C of 71% for the twice-weekly dose and 63% for the once-monthly dose compared to placebo ($P < .0001$). In addition, 90% of evolocumab-treated patients achieved LDL-C <70 mg/dL. The Durable Effect of PCSK9 Antibody Compared with Placebo Study (DESCARTES) was a randomized, double-blind, placebo-controlled 52-week trial comparing evolocumab versus placebo in 901 patients on background lipid-lowering therapy.[174] Background therapy included atorvastatin 80 mg with or without ezetimibe 10 mg daily. Of the entire study population, 139 patients had ASCVD. Evolocumab was administered 420 mg SQ once monthly. The results showed that in patients with ASCVD who received evolocumab, the mean percent LDL-C reduction was 54% ($P < .0001$). Alirocumab was evaluated in the COMBO study.[175] This was a multicenter, double-blind, placebo-controlled trial that randomly assigned patients to alirocumab or placebo in addition to maximally tolerated doses of statins with or without additional lipid-lowering therapy who required additional LDL-C lowering. The dose of alirocumab was 75 mg every 2 weeks. If additional LDL-C lowering was still needed at 12 weeks, the dose of alirocumab was increased to 150 mg every 2 weeks and continued for another 12 weeks. At 24 weeks, the mean reduction in LDL-C with alirocumab was 44% compared to 2% with placebo ($P < .0001$). A significant portion (84%) of the study population had ASCVD. After 12 weeks, the mean reduction in LDL-C from baseline was 45% versus 1% with placebo. Alirocumab has been evaluated in the Long-Term Safety and Tolerability of Alirocumab in High Cardiovascular Risk Patients with Hypercholesterolemia Not adequately Controlled with Their Lipid Modifying Therapy (ODYSSEY LONG TERM) trial in 2341 patients at high risk for CHD.[176] Patients were randomly assigned alirocumab 150 mg twice weekly to placebo in addition to maximum tolerated statin therapy with or without additional lipid-lowering therapy. Patients with ASCVD composed 69% of the trial. At 24 weeks, the percent change in LDL-C reductions with alirocumab

compared to placebo was 58% ($P < .0001$). This reduction in LDL-C was sustained over a 78-week treatment period.

The FOURIER (Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk) was the first trial published to demonstrate reduction in CV outcomes with the addition of a PCSK9 inhibitor.[177] This was a randomized, double-blind, placebo-controlled trial that included 27,564 patients age 40 to 85 years with clinical ASCVD. Patients were included if they had ASCVD defined as either MI, nonhemorrhagic stroke, or symptomatic PAD. Study subjects were also required to have at least one major ASCVD risk factor or two minor risk factors. The minor risk factors were defined as a history of non–MI-related coronary revascularization, residual CAD with ≥40% stenosis in two or more large vessels, HDL-C <40 mg/dL for males and <50 mg/dL for females, hs-CRP >2 mg/L, LDL-C ≥130 mg/dL or non-HDL-C ≥160 mg/dL, or metabolic syndrome. Patients also had to have a fasting LDL-C level >70 mg/dL or a non–HDL-C levels ≥100 mg/dL after ≥4 weeks of stable dose of atorvastatin 20, 40, or 80 mg daily, with or without ezetimibe, and fasting TG ≤400 mg/dL. The median LDL-C at baseline was 92 mg/dL. Patients were randomized to receive evolocumab administered SQ at a dose of 140 mg every 2 weeks (or 420 mg monthly) or matching placebo. The median duration of therapy was 2.2 years. The results demonstrated that treatment with evolocumab significantly reduced the risk of the primary end point (composite of CV death, MI, stroke, hospitalization for UA, or coronary revascularization) (HR, 0.85; 95% CI, 0.79–0.92, $P < .001$) and the key secondary end point (CV death, MI, or stroke) (HR, 0.80; 95% CI, 0.73–0.88; $P < .001$). The degree of risk reduction in CV death, MI, or stroke increased over time, from 16% in the first year of follow-up to 25% after 1 year. In terms of LDL-C reduction, at 48 weeks, the mean LDL-C was reduced by 59% (mean 56 mg/dL). Approximately 87% of patients achieved an LDL-C of <70 mg/dL. In addition, 67% of patients had LDL-C levels <40 mg/dL, and 42% reached levels of <25 mg/dL. There was a slightly higher rate of injection site reactions in the patients receiving evolocumab compared with placebo (2.1% vs 1.6%).

The ODYSSEY Outcomes trial was a multicenter, double-blind, placebo-controlled trial that evaluated the effect of alirocumab on CV outcomes in 18,924 patients with a recent ACS (MI or UA within the past 1–12 months).[178] Additional inclusion criteria included an LDL-C ≥70 mg/dL, non–HDL-C ≥100 mg/dL, and apo B of ≥80 mg/dL. Mean baseline LDL-C was 92 mg/dL, and all patients were on background statin therapy. Patients were randomized in a 1:1 manner to receive alirocumab 75 mg SQ or placebo every 2 weeks. The median duration of follow-up was 2.8 years. The primary end point was a composite of death from CHD, nonfatal MI, fatal or nonfatal ischemic stroke, or UA requiring hospitalization. The primary end point occurred in 9.5% in the alirocumab group and in 11.1% in the placebo group (HR, 0.85; 95%, CI, 0.78–0.93; $P < .001$). The mean LDL-C achieved with alirocumab at 48 months was 53 mg/dL, equating to an average reduction of 54.7%. The results of this trial demonstrate that the benefit is likely a class effect and that obtaining dramatically low levels of LDL-C does not appear to result in adverse effects. However, longer term data will be needed to confirm these results.

Both alirocumab and evolocumab have been evaluated in patients with HeFH.[179–181] All patients in these studies were on maximally tolerated doses of statins. In the combined studies evaluating alirocumab, patients had an average baseline LDL-C of 141 mg/dL. Patients were treated for 12 weeks with alirocumab 75 mg every 2 weeks or placebo. At the end of the treatment period, the mean LDL-C reduction observed with alirocumab was 48%. As with other studies with alirocumab, if additional LDL-C lowering was needed, patients were given an additional 12 weeks of therapy with an increased dose of 150 mg every 2 weeks. Following an additional 12 weeks of treatment, the mean LDL-C reduction from baseline was 54% ($P < .0001$). Almost half (42%) of the study population received the higher dose. Evolocumab was evaluated in the patient population in the RUTHERFORD-2 trial.[181] Patients were randomized to receive 140 mg every 2 weeks of evolocumab, or 420 mg once monthly or placebo. The mean baseline LDL-C was 156 mg/dL, with 76% on high-intensity statin therapy. Following 12 weeks of therapy,

evolocumab reduced baseline LDL-C by 61% with twice-weekly dosing and 62% with monthly dosing ($P < .0001$).

Evolocumab has been studied in patients with HoFH in the Trial Evaluating PCSK9 Antibody in Subjects with LDL Receptor Abnormalities (TESLA Part B).[182] This was a multicenter, double-blind, randomized, placebo-controlled 12-week trial in 49 patients. Patients received 420 mg monthly of evolocumab or placebo. The mean LDL-C at baseline was 349 mg/dL. All patients were on either atorvastatin or rosuvastatin, with 92% also being on ezetimibe. Following 12 weeks of treatment with evolocumab, the mean decrease in LDL-C from baseline was 31% ($P < .0001$).

PHARMACOKINETICS/PHARMACODYNAMICS

Alirocumab and evolocumab are both human monoclonal immunoglobulin g2 (IGg2) antibodies and, therefore, must be administered via SQ injection to exert an effect. Maximum suppression of PCSK9 occurs in ~4 hours with evolocumab and 4 to 8 hours with alirocumab. Maximum serum concentrations reached in 3 to 4 days with evolocumab and 3 to 7 days with alirocumab. The volume of distribution for both agents is small; therefore, these agents are expected to stay in the extracellular space. Alirocumab is eliminated through degradation to small peptides and amino acids, whereas evolocumab is cleared based on its concentration. At low concentrations, it is cleared primarily through saturable binding to PCSK9, and at higher concentrations, it is eliminated via a nonsaturable proteolytic pathway. The half-life of alirocumab is 17 to 20 days and 11 to 17 days for evolocumab.

ADVERSE EFFECTS

The most common adverse effects reported in the 52 weeks study with evolocumab were nasopharyngitis, upper respiratory tract infection, influenza, back pain, and injection site reactions. However, the difference in the incidence compared to placebo is relatively small. The most common injection site reactions were erythema, pain, and bruising. The most common adverse effect leading to

discontinuation was myalgia that occurred in 0.3% of evolocumab patients and 0% in those receiving placebo. In pooled studies, the types of adverse effects reported were relatively similar. Allergic reactions occurred in 5.1% of evolocumab-treated patients and 4.6% in those treated with placebo. Neurocognitive events were reported in less than 0.2% of patients. Hypersensitivity reactions such as rash and urticaria were also reported in 1% and 0.4%, respectively, with cases resulting in discontinuation of therapy. The adverse reactions reported with alirocumab were nasopharyngitis, injection site reactions, influenza, and urinary tract infection. The main adverse effects associated with discontinuation were allergic reactions (0.6% vs 0.2% for placebo) and elevated liver enzymes (0.3% vs <0.1% for placebo). Injection site reactions were similar to those reported with evolocumab. Neurocognitive events were reported in 0.8% of patients treated with alirocumab compared to 0.7% for placebo. Hypersensitivity reactions also occurred with alirocumab. However, hypersensitivity vasculitis as well as hypersensitivity reactions requiring hospitalizations were reported with alirocumab, but not with evolocumab. Neutralizing antibodies were detected in 1.2% of patients treated with alirocumab, and no cases were reported in patients taking evolocumab. However, the long-term consequences from developing neutralizing antibodies are currently unknown.

PLACE IN THERAPY

Both alirocumab and evolocumab are indicated as an adjunct to diet and maximally tolerated statin therapy in patients with HeFH or clinical ASCVD, who require additional reductions in LDL-C. These agents should be considered as add-on therapy to either patients already on statin therapy who need additional LDL-C lowering or in patients who are deemed statin intolerant.[100] Evolocumab is also indicated for use in combination with other lipid-lowering therapies including LDL apheresis in patients with HoFH who require additional lowering in LDL-C. Alirocumab is administered as a dose of 75 mg every 2 weeks and may be increased in 4 to 8 weeks to 150 mg every 2 weeks if additional LDL-C lowering is required. Evolocumab

is dosed at 140 mg every 2 weeks or 420 mg once monthly for HeFH and those with primary hypercholesterolemia with clinical ASCVD. In patients with HoFH, the dose is 420 mg once monthly. Alirocumab has only been studied in patients age older than 18 years, whereas evolocumab may be used in the adolescent population with HoFH ages 13 to 17 years. Neither agent requires a dose adjustment in patients with mild-to-moderate renal insufficiency. No data are available for patients with creatinine clearance (CrCl) <30 mL/min. Because these proteins do not rely upon the kidneys as a method of excretion, they can likely be used in patients with low CrCl, including those undergoing hemodialysis. However, the PCSK9 inhibitors have not been studied in this patient population. In addition, because they are large molecules, it is unlikely they would be removed by hemodialysis. No dose adjustment is necessary in patients with hepatic impairment.

Current guidelines recommend consideration for the addition of a PCSK9 in the following situations: (a) patients with established ASCVD who are judged to be at very high risk for recurrent events and LDL-C above the threshold of 70 mg/dL despite high-intensity or maximally tolerated statin therapy, (b) patients with severe primary hypercholesterolemia (LDL-C ≥190 mg/dL) with LDL-C above the threshold of 100 mg/dL on treatment with a statin plus ezetimibe, and (c) patients ages 40 to 75 years with a baseline LDL-C ≥220 mg/dL with LDL-C above the threshold of 130 mg/dL on statin and ezetimibe therapy.[5]

CLINICAL PEARLS

- Allow evolocumab injections to warm at room temperature for at least 30 minutes before use and alirocumab 30 to 40 minutes before use.
- Do not warm evolocumab by any other means than setting at room temperature (eg, rolling between hands).
- If you miss a dose of evolocumab and the time to next dose is >7 days, administer the dose. If <7 days, hold the dose and get back on usual schedule.

- Evolocumab and alirocumab may be injected into the thigh, abdomen, or the upper arm.
- Evolocumab can remain at room temperature but expires in 30 days.
- Alirocumab should not be left unrefrigerated for >24 hours.

Bempedoic Acid

MECHANISM OF ACTION

Bempedoic acid is an adenosine triphosphate-citrate lyase (ACL) inhibitor. ACL is an enzyme that works upstream of 3-hydroxy-3-methyl-glutaryl-coenzyme reductase in the cholesterol biosynthesis pathway. Inhibition of ACL results in decreased cholesterol synthesis in the liver and lowers LDL-C in blood via upregulation of LDL receptors.

EFFICACY

Several phase 3 trials, known as the CLEAR trials (Cholesterol Lowering via Bempedoic Acid, an ACL-Inhibiting Regimen), have evaluated the effects of bempedoic acid in patients at high CV risk as well as those with a history of intolerance to statin therapy.[183–185] CLEAR Serenity trial was a double-blind, placebo-controlled trial that evaluated the efficacy of bempedoic acid in patients with hypercholesterolemia and a history of intolerance to at least two statins.[183]A total of 345 patients were randomized to either bempedoic acid 180 mg or placebo once daily for 24 weeks. The primary end point was mean percent change in LDL-C from baseline to week 12. The mean baseline lipoproteins were a mean LDL-C of 157.6 mg/dL, non–HDL-C 192.6 mg/dL, TC 244.2 mg/dL, and apo B of 141.3 mg/dL. The results demonstrated a significant reduction in LDL-C with bempedoic acid compared to placebo (−23.6% vs −1.3%, $P < .001$). Significant reductions with bempedoic acid versus placebo were also observed for non–HDL-C (−17.9%), TC (−14.8%), and apo B (−15.0%) ($P < .001$). Overall, bempedoic acid was well

tolerated. Bempedoic acid offers a safe and effective oral therapeutic option for lipid lowering in patients who cannot tolerate statins.

The CLEAR Wisdom trial evaluated bempedoic acid versus placebo in 779 patients with ASCVD or HeFH, or both.[184] This was a double-blind, placebo-controlled trial in which patients were randomized to bempedoic acid 180 mg or placebo in addition to maximally tolerated statin therapy. The primary end point was percent change in LDL-C from baseline at 12 weeks, with a secondary end point of changes from baseline of other lipid parameters and biomarkers. The median lipoprotein parameters at baseline were an LDL-C of 120.4 mg/dL, non–HDL-C of 152 mg/dL, apo B of 117 mg/dL, TC 203 mg/dL, and hs-CRP of ~1.75 mg/L. Treatment with bempedoic acid for 12 weeks resulted in a significant reduction in LDL-C (15.1%) compared to placebo (2.4%; $P < .001$). Significant reduction in other lipid parameters were also observed with bempedoic acid: TC (−9.9% vs 1.3 %; $P < .001$), apo B (−9.3% vs 3.7%, $P < .001$), and non–HDL-C (−10.8% vs −2.3%, $P < .001$). Bempedoic acid demonstrated a positive benefit in lowering LDL-C in patients already taking statin therapy.

The CLEAR Harmony trial was the largest of these trials.[185] A total of 2230 patients with ASCVD and/or HeFH and an LDL-C ≥70 mg/dL were randomized to bempedoic acid 180 mg or placebo. The primary end point was overall safety, whereas the secondary endpoint was efficacy that was assessed by percent change in LDL-C from baseline to 12 weeks. The mean baseline LDL-C was 103 mg/dL. The results at week 12 demonstrated a mean reduction in LDL-C by 16.5% from baseline, 18.1 percentage points more than with placebo ($P < .001$). At weeks 24 and 52, bempedoic acid was associated with greater percent LDL-C lowering compared to placebo of 16.1% and −13.6%, respectively ($P < .001$). Although CV events were reported and the adjudicated major CV events occurred at a lower rate in the bempedoic acid group compared to placebo (4.6% and 5.7%, respectively), the trial was too short and underpowered to look at outcomes. However, CV outcomes trials are ongoing. In terms of safety, bempedoic acid was associated with more adverse events

leading to discontinuation (10.9% vs 7.1%, *P* = .005) as well as a higher incidence of gout (1.2% vs 0.3%, *P* = .03).

Bempedoic acid has also been evaluated in combination with ezetimibe in patients with clinical ASCVD or HeFH and baseline LDL-C ≥100 mg/dL, or those with multiple CV risk factors and an LDL-C ≥130 mg/dL. All were receiving maximum tolerated doses of statins, which could have included no statin treatment. The primary end point was a change in LDL-C at 12 weeks, with a mean LDL-C at baseline ranging from 145 to 154 mg/dL. The results demonstrated a significant reduction in LDL-C with the bempedoic acid/ezetimibe combination (−36.2%), compared to bempedoic acid alone (−17.2%) or ezetimibe monotherapy (−23.2%), *P* < .001 for all comparisons). As in other trials, significant reductions in other lipid parameters were also observed with the combination or either as monotherapy.

PHARMACOKINETICS/PHARMACODYNAMICS

Bempedoic acid is metabolized through acyl glucuronide and is converted to an active metabolite. Following oral administration, the drug reaches peak levels in ~3 hours and reaches steady state after 7 days. The mean half-life is 21 +/11 hours at steady state. When evaluated in patients with mild, moderate, or severe renal impairment, the AUC of bempedoic acid increased by 1.5-, 2.3-, and 2.4-fold, respectively. It is important to note that clinical trials did not include patients with severe renal impairment (eGFR <30 mL/min) or patients on hemodialysis. In patients with moderate hepatic impairment, a lower AUC was observed in those taking bempedoic acid; however, this is not considered to be clinically significant. There are no data in patients with severe hepatic impairment.

ADVERSE EFFECTS

Increased uric acid levels were more common in patients taking bempedoic acid. The proposed mechanism is due to inhibition of tubular OAT2 by this agent, resulting in increased uric acid levels. The increase usually occurs within the first 4 weeks of treatment.

This increase in uric acid may increase the risk of gout, with a higher incidence reported in those with a prior history. Patients should be monitoring for gout symptoms upon initiation of therapy.

There is also a risk of tendon rupture that has been reported. In clinical trials, the incidence was 0.5% for bempedoic acid compared to placebo (0%). Patients who appear to be at higher risk are those over the age of 60, taking corticosteroids, fluoroquinolone antimicrobials, renal failure, and those with a prior history of tendon disorders.

PLACE IN THERAPY

Bempedoic acid is indicated as an adjunct to diet and maximally tolerated statin therapy for the treatment of adults with HeFH or established ASCVD who require additional LDL-C lowering. Current guidelines have not yet been updated to provide clinicians with where this agent fits into therapy. However, until results of CV outcomes are available, its role is likely limited to patients who are deemed high risk and not able to achieve their target LDL-C despite treatment with other agents.

CLINICAL PEARLS

- Limit the dose of simvastatin to 20 mg when combined with bempedoic acid.
- Limit the dose of pravastatin to 40 mg when combined with bempedoic acid.
- May be administered with or without food
- Currently available as a combination tablet containing ezetimibe
- Avoid use in patients with a history of tendon rupture.

Inclisiran

MECHANISM OF ACTION

Inclisiran is a first in class small interfering RNA (siRNA) agent designed to lower LDL-C. Following uptake into the hepatocytes,

inclisiran binds to liver-expressed asialoglycoprotein receptors. Inclisiran also contains a guide strand, and therefore once in the hepatocyte, it is loaded into the RNA-induced silencing complex (RISC) and inhibits translation of the PCSK9 protein. The end result is a reduction in LDL-C secondary to an increase in LDL receptor density and increase in LDL-C uptake and clearance.

EFFICACY

Inclisiran has been evaluated in a number of trials, including ORION I.[186] This was a placebo-controlled, double-blind, randomized phase 2, multiple-ascending-dose trial that evaluated the efficacy of inclisiran in 501 patients at high risk for ASCVD. All patients were on maximum tolerated doses of statins and subsequently randomized to either a single dose or double dose of inclisiran or placebo. The primary end point was the change from baseline in LDL-C. At the end of the study period of 180 days, inclisiran demonstrated a dose-dependent reduction in LDL-C with mean reductions of 41.9% following a single dose of inclisiran compared to a 2.1% increase with placebo and a 52.5% reduction after the two-dose regimen for inclisiran compared to a 1.8% increase for placebo ($P < .001$). ORION 10 and ORION 11 and two phase 3 trials evaluated the efficacy of inclisiran in patients with ASCVD or an ASCVD risk equivalent with elevated LDL-C (≥70 mg/dL in ORION 10 and ≥100 mg/dL in ORION 11).[187] Patients were also required to be on maximum tolerated statin therapy for at least 30 days. A total of 3178 patients were randomized 1:1 to receive either 284 mg of inclisiran administered by SQ injection or placebo. Doses were administered on days 1, 90, and then every 6 months for up to 540 days. The co-primary end points in each trial were the placebo-corrected percentage change in LDL-C from baseline to day 510 as well as time-adjusted percentage change in LDL-C from baseline after day 90 and up to day 540. The results demonstrated a mean reduction in LDL-C at day of 52.3% for inclisiran in the ORION 10 trial and 49.9% in the ORION 11 trial ($P < .001$). These data suggest that administering inclisiran once every 6 months will provide a sustained

reduction in LDL-C. To date, all trials evaluating inclisiran have demonstrated significant reductions in LDL-C across a variety of patient populations, all of whom were on maximum tolerated doses of statin therapy.

PHARMACOKINETICS/PHARMACODYNAMICS

Inclisiran is administered via subcutaneous injection at a dose of 284 mg initially, then repeated at 3 months, followed by every 6 months thereafter. After a single subcutaneous dose, the volume of distribution is approximately 5 L, with a half-life of 9 hours.[188] Inclisiran is not a substrate for CYP450 or transporters and is primarily metabolized by nucleases to shorter nucleotides. Although no formal drug-drug interaction studies have been conducted, due to the nature of its metabolism, no clinical significant drug interactions are anticipated. Approximately 16% undergoes renal elimination and no dose adjustments are needed in patients with mild-to-severe renal function. No data is available regarding use in patients with end stage renal disease. No dose adjustment are needed in patients with mild-to-moderate hepatic dysfunction, however, inclisiran has not been studied in patients with severe hepatic impairment.

ADVERSE EFFECTS

The adverse effects attributed to inclisiran in clinical trials were relatively minor with injection site reactions being the most common. Other adverse effects that occurred with $\geq$3% incidence included arthralgia, diarrhea, dyspnea, urinary tract infection, pain in extremity, and bronchitis.[186,187]

PLACE IN THERAPY

Inclisiran recently received FDA approval as an adjunct to diet in patients with ASCVD and heterozygous FH with elevated LDL-C despite maximally tolerated statin doses. Based on the trial results, this agent shows potential promise as an additional agent in our armamentarium to lower LDL-C. However, its overall role in clinical practice will be further defined based on the CV outcomes trial

ORION-4 that is currently underway. This trial will evaluate the CV outcomes with inclisiran at 180 sites in 15,000 patients with ASCVD.[189]

CLINICAL PEARLS

- The medication should be given initially then an additional dose given 3 months later, followed by every 6 months
- Inclisiran should be discontinued once pregnancy is recognized
- No data in the pediatric population currently available

Evinacumab

MECHANISM OF ACTION

Evinacumab is a recombinant human IgG4 monoclonal antibody that binds to and inhibits angiopoietin life protein 3 (ANGPTL3). By blocking ANGTPL3, the catalytic activity of LPL and endothelial lipase is disinhibited, resulting in a reduction in TGs, LDL-C, and non–HDL-C.[190] The reductions in LDL-C occur independently of the presence of LDL receptor. This is likely due to the promotion of VLDL processing and upstream clearance of LDL formation, secondary to the inhibition of endothelial lipase activity.[191]

EFFICACY

The Evinacumab Lipid Studies in Patients with Homozygous Familial Hypercholesterolemia (ELIPSE HoFH) trial was a placebo-controlled study to evaluate evinacumab in patients with HoFH.[192] A total of 65 patients were randomized to receive either evinacumab administered via intravenous (IV) infusion at a dose of 15 mg/kg every 4 weeks or placebo. Of note, 53 of the patients enrolled had a genetically confirmed diagnosis of HoFH. The mean baseline LDL-C was 255.2 mg/dL. All patients were receiving background lipid-lowering therapy. Of these, 94% receiving statin therapy, of which 77% were high intensity, 77% were receiving a PCSK9 inhibitor, 75% ezetimibe, 25% lomitapide, and 34% were undergoing apheresis. The primary outcome was the percent change in LDL-C from baseline to week 24

of treatment.[192] The results demonstrated a significant 47.1% reduction in LDL-C in those treated with evinacumab compared to a 1.9% increase in the placebo group ($P < .001$), a mean difference of 49%. With regard to the LDL-C reduction, in patients treated with evinacumab, 47% achieved an LDL-C of <100 mg/dL, with the majority (56%) achieving at least a 50% reduction from baseline. Reductions in other lipoprotein parameters including apo B (41.4%), non–HDL-C (49.7%), and TC (47.4%) ($P < .001$) were also observed.[192]

There are additional trials that are ongoing to further evaluate the efficacy of evinacumab in various patient populations, including patients with HeFH or non-HeFH with a history of ASCVD; those with persistent hypercholesterolemia (LDL-C ≥70 mg/dL) with clinical ASCVD, or ≥100 mg/dL without clinical ASCVD, HoFH, or hypertriglyceridemia; and in the pediatric patient population (ages 5−11 years with HoFH).

PHARMACOKINETICS/PHARMACODYNAMICS

Evinacumab is administered by IV injection at a dose of 15 mg/kg every 4 weeks and reaches steady-state concentration after 4 doses. The volume of distribution is ~4.8 L, and the half-life is dependent upon serum concentration and is, therefore, variable.[190] Based on pharmacokinetic analysis, the time for serum concentrations of evinacumab to fall below the lower limit of quantification is ~19 weeks following the last steady-state dose.[190] The exact metabolic pathway of metabolism for evinacumab has not been fully elucidated, however; but most likely, it is degraded into small peptides and amino acids via catabolic pathways.[190,193] Evinacumab does not undergo renal excretion with no impact on concentrations in patients with mild-to-moderate renal insufficiency. There are no data on the use of evinacumab in patients with severe renal impairment or in patients with hepatic impairment.

ADVERSE EFFECTS

Adverse effects observed in clinical trials with evinacumab were minimal and rarely led to discontinuation of therapy. The most common adverse effects reported (occurring in >3% of patients) and with greater frequency than placebo included nasopharyngitis, flulike illness, dizziness, nausea, asthenia, pain in extremity, and rhinorrhea.

PLACE IN THERAPY

Evinacumab has been approved by the FDA for use in the treatment of HoFH for adults and pediatric patients age 12 years or older. However, these indications will likely expand based on the results of ongoing clinical trials. Currently, in the absence of CV outcomes data, the use of evinacumab in clinical practice should be reserved as an adjunctive treatment option in patients who require additional LDL-C lowering despite being optimized on cholesterol-lowering therapies that have demonstrated benefit.

CLINICAL PEARLS

- The medication should be given at 4-week intervals.
- A negative pregnancy test should be confirmed before therapy initiation.
- Birth control should be utilized for at least 5 months following last dose of evinacumab.

Essential Hypertension

Judy W. Cheng

CORE PRINCIPLES		CHAPTER CASES
1	A diagnosis of hypertension is based on the mean of two or more properly measured seated blood pressure (BP) measurements taken on two or more occasions.	**Case 9-1 (Questions 3-5), Tables 9-1, 9-4, Figure 9-1**
2	Patients with hypertension have a recommended BP 140/90 mm Hg threshold for initiation of pharmacologic therapy if their atherosclerotic cardiovascular disease (ASCVD) risk is ≤10%. Patients with atherosclerotic heart disease (coronary artery disease, stroke, peripheral arterial disease) or whose ASCVD is ≥10% have a BP threshold for pharmacologic treatment of >130/80 mm Hg.	**Case 9-1 (Questions 6–8)**
		Case 9-1 (Questions

		11–13), Table 9-5
3	Lifestyle modifications are the foundation for preventing hypertension, and they are an important component of first-line therapy in all patients treated with antihypertensive drug therapy.	
4	Evidence supports the use of an angiotensin-converting enzyme inhibitor (ACEI), angiotensin-receptor blocker (ARB), calcium channel blocker (CCB), or thiazide diuretic as first-line therapy to prevent cardiovascular (CV) events for most patients.	**Case 9-1 (Questions 9, 14, 15)** **Case 9-3 (Question 2)** **Case 9-4 (Questions 1–9)** **Case 9-6 (Questions 1, 2, 6–10), Tables 9-8, 9-9, 9-11, 9-12, 9-13**
5	In the Black population, including those with diabetes, evidence supports the use of thiazide diuretics and CCBs as first-line treatment.	**Case 9-1 (Questions 16, 17)** **Case 9-5 (Question 1-3, 6-10)**
6	Pharmacotherapy recommendations for patients with hypertension and other comorbidities are specifically based on evidence demonstrating reduced risk of CV events.	**Case 9-1 (Question 10)** **Case 9-3 (Questions 2, 4)** **Case 9-6 (Question 2), Table 9-7**
7	Elderly patients with hypertension and no other comorbidity should be managed using the same general treatment principles and have a BP goal similar to that of other patients with hypertension. However, clinicians should implement careful titration of antihypertensive therapy and monitoring plan in those with high comorbidity burden, because they may be more	**Case 9-2 (Questions 1, 2)**

	sensitive to the BP-lowering effects of antihypertensive agents.	
8	In the population age 18 years or older with chronic kidney disease (CKD) and those age older than 70 years, evidence supports initial (or add-on) antihypertensive treatment to include an ACEI or ARB to improve renal outcomes. This applies to all patients with CKD with hypertension regardless of race or diabetes status.	**Case 9-3 (Questions 1, 3)** **Case 9-5 (Question 5)**
9	If goal BP is not attained within a month of treatment, increase the dose of the initial drug, or add a second drug (ACEI, ARB, CCB, or thiazide diuretic). If goal BP cannot be reached with two drugs, add and titrate a third drug. If goal BP cannot be reached using only the drugs recommended as first line, because of a contraindication or the need to use more than three drugs to reach goal BP, antihypertensive drugs from other classes can be used. Referral to a hypertension specialist may be indicated.	**Case 9-4 (Question 10)** **Case 9-6 (Question 1)** **Case 9-7 (Questions 1–3)** **Case 9-8 (Questions 1–4)** **Case 9-9 (Questions 1–3)** **Case 9-10 (Questions 1–3)** **Case 9-11 (Questions 1–4), Tables 9-2, 9-3, 9-10, 9-14, 9-15**

INTRODUCTION

In 2016, approximately 46% of the U.S. population (149 million people) had hypertension, also called high blood pressure (BP).[1] About 53% of those used antihypertensive medication, but only 25% of those were controlled (defined as both systolic blood pressure

[SBP] <140 mm Hg and diastolic blood pressure [DBP] <90 mm Hg). Hypertension is also one of the most significant risk factors for cardiovascular (CV) morbidity and mortality resulting from target-organ damage to blood vessels in the heart, brain, kidney, and eyes. These complications can manifest as either atherosclerotic vascular disease or other forms of CV disease. The exact etiology of essential hypertension is unknown; however, lifelong management with lifestyle modifications and pharmacotherapy are usually needed.

Blood Pressure

During systole, the left ventricle contracts, ejecting blood systemically into the arteries and causing a sharp rise in arterial BP. This is SBP. The left ventricle then relaxes during diastole, and arterial BP decreases to a trough value as blood returns to the heart from the venous system. This is DBP. When recording BP (eg, 120/76 mm Hg), the numerator is the SBP, and the denominator is the DBP. BP has a predictable diurnal rhythm, with fluctuations throughout the day. Values are lowest during the nighttime, sharply rise starting in the early morning, and peak in the late morning to early afternoon.

Mean arterial pressure (MAP) is sometimes used to represent BP, especially in patients with a hypertensive emergency. MAP collectively reflects both SBP and DBP, with one-third of the pressure from SBP and two-thirds from DBP. It is calculated using the following equation (Eq. 9-1):

$$\mathrm{MAP} = (\mathrm{SBP} \times 1/3) + (\mathrm{DBP} \times 2/3) \qquad \textbf{(Eq. 9-1)}$$

Hypertension is defined as an elevated SBP, DBP, or both. A clinical diagnosis of hypertension is based on the mean of two or more properly measured seated BP measurements taken on two or more occasions. Since 1976, the National Heart Lung and Blood Institute (NHLBI) has collaborated with researchers and practitioners to develop clinical practice guidelines focused on the management of hypertension (the Joint National Commission [JNC]). In late 2013,

the eighth edition of the JNC guidelines was released.[2] Unlike previous editions of the JNC guidelines, definitions and staging of BP were not addressed, but thresholds for pharmacologic treatment were defined. Furthermore, in 2017, the American College of Cardiology (ACC) and American Heart Association (AHA) collaborated with the NHLBI and stakeholder and professional organizations to publish hypertension treatment guidelines. These guidelines further define BP definition and treatment goals in patients with different CV risk factors and diseases.[3]

PATHOPHYSIOLOGY OF BLOOD PRESSURE REGULATION

Various neural and humoral factors are known to influence and regulate BP.[4] These include the adrenergic nervous system (controls α- and β-adrenergic receptors), the renin–angiotensin–aldosterone system (RAAS) (regulates systemic and renal blood flow), renal function and renal blood flow (influences fluid and electrolyte balance), several hormonal factors (adrenal cortical hormones, vasopressin, thyroid hormone, and insulin), and the vascular endothelium (regulates release of nitric oxide [NO], bradykinin, prostacyclin, and endothelin). BP is normally regulated by compensatory mechanisms that respond to changes in cardiac demand. An increase in cardiac output (CO) normally results in a compensatory decrease in total peripheral resistance (TPR); likewise, an increase in TPR results in a decrease in CO. These events regulate MAP, as is represented in the following equation (Eq. 9-2):

$$\mathrm{MAP} = \mathrm{CO} \times \mathrm{TPR} \qquad \textbf{(Eq. 9-2)}$$

Adverse changes in BP can occur when these compensatory mechanisms do not function properly. It has been suggested that in hypertension an initial increase in fluid volume increases CO and arterial pressure. Eventually, with long-standing hypertension, it is believed that TPR increases so that CO returns to normal.

The kidney plays an important role in the regulation of arterial pressure, especially through the RAAS. Decreases in BP and renal

blood flow, volume depletion or decreased sodium concentration, and an activation of the sympathetic nervous system can all trigger an increased secretion of the enzyme renin from the cells of the juxtaglomerular apparatus in the kidney. Renin acts on angiotensinogen to catalyze the formation of angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II (see Figs. 14-2 and 14-6 in Chapter 14, Heart Failure). Angiotensin II is a potent vasoconstrictor that acts directly on arteriolar smooth muscle and also stimulates the production of aldosterone by the adrenal glands. Aldosterone causes sodium and water retention and the excretion of potassium. Several factors influence renin release, especially those that alter renal perfusion. The resultant increase in BP results in suppression of renin release through negative feedback.

Arterial BP is also regulated by the adrenergic nervous system, which causes contraction and relaxation of vascular smooth muscle. Stimulation of α-adrenergic receptors in the central nervous system (CNS) results in a reflex decrease in sympathetic outflow, causing a decrease in BP. Stimulation of postsynaptic α_1-receptors in the periphery causes vasoconstriction. The α-receptors are regulated by a negative feedback system; because norepinephrine is released into the synaptic cleft and it stimulates presynaptic α_2-receptors, further norepinephrine release is inhibited. This negative feedback results in a balance between vasoconstriction and vasodilatation. Stimulation of postsynaptic β_1-receptors located in the myocardium causes an increase in heart rate and contractility, whereas stimulation of postsynaptic β_2-receptors in blood vessels results in vasodilation.

A direct association exists between sodium and BP. Although there is a considerably high degree of patient variability in BP sensitivity to sodium (likely affected by heredity and interactions with other environmental exposures), patients with a high dietary sodium intake generally have a greater prevalence of hypertension than those with a low sodium intake. The mechanism by which excess sodium intake contributes to hypertension is uncertain, but it is

believed to involve an undetermined natriuretic hormone (not the A- and B-type natriuretic peptides associated with heart failure) that may be induced as a consequence of impaired renal sodium excretion. This natriuretic hormone might also cause an increase in intracellular sodium and calcium, resulting in increased vascular tone and hypertension. Epidemiologic evidence and clinical trials have demonstrated an inverse relationship between calcium and BP. One proposed mechanism for this relationship involves an alteration in the balance between intracellular and extracellular calcium. Increased intracellular calcium concentrations can increase peripheral vascular resistance (PVR), resulting in increased BP.

A decrease in dietary potassium has been associated with an increase in PVR. In theory, diuretic-induced hypokalemia could counteract some of the antihypertensive effects of diuretic therapy, but this has not been seen in clinical trials. It is important, however, that potassium concentrations be maintained within the normal range because hypokalemia increases the risk of CV events, such as sudden death.

Insulin resistance and hyperinsulinemia also have been associated with hypertension. Kaplan[4] suggests that insulin resistance is responsible for the frequent coexistence of hyperglycemia, dyslipidemia, hypertension, and abdominal obesity (called *metabolic syndrome*).[5] The exact role of insulin resistance in the development of hypertension is still evolving.

The vascular epithelium is a dynamic system in which vascular tone is regulated by numerous substances. As noted previously, angiotensin II promotes vasoconstriction of the vascular epithelium. However, several other substances regulate vascular tone. NO is produced in the endothelium and is a potent vasodilatory chemical that relaxes the vascular smooth muscle. Hypothetically, some patients with hypertension have an intrinsic deficiency in NO release and inadequate vasodilation, which could contribute to hypertension and its vascular complications.

Factors that regulate BP are well understood and continue to evolve, but the cause of essential hypertension is still unknown. It is impossible to target therapy to specific abnormalities. Therefore,

antihypertensive therapy should be selected based on evidence from clinical trials that have demonstrated reductions in hypertension-associated complications, as is discussed later in this chapter.

CARDIOVASCULAR RISK AND BLOOD PRESSURE

Direct correlations between BP values and risk of CV disease have been established based primarily on epidemiologic data. Beginning at a benchmark BP of 115/75 mm Hg, the risk of CV disease doubles with every increment of 20/10 mm Hg.[5] Clinically, it is important to note that incremental elevations in SBP are more predictive of CV disease than are elevations in DBP, especially for patients older than 50 years of age. Therefore, SBP is the target of evaluation and intervention for most patients with hypertension. In younger patients with hypertension, elevated DBP may be the only BP abnormality present.

MEASURING BLOOD PRESSURE

Auscultatory method

The measurement of BP should be standardized to minimize variability in readings. The AHA technique for auscultatory BP measurement (**Table 9-1**)[6] should be used in most patients.[7]

Table 9-1

Auscultatory Method for Blood Pressure Measurement in Adults as Recommended by the American Heart Association

Patient: Patient should be seated for 5 minutes with arm bared, unrestricted by clothing, and supported at heart level. Smoking or food ingestion should not have occurred in the 30 minutes before the measurement.

Cuff: An appropriately sized cuff should be used. The internal inflatable bladder width should be at least 40% of the bladder length and cover at least 80% of the upper arm circumference. The cuff should be wrapped snugly around the arm, with the center of the bladder over the brachial artery.

Monitor: Measurements should be taken with a correctly calibrated mercury sphygmomanometer, an aneroid manometer, or a validated electronic device.

Palpatory method: SBP should be estimated using the palpatory method. The cuff is rapidly inflated in 10 mm Hg increments, while simultaneously palpating the radial pulse on the patient's wrist on the cuffed arm and observing the

manometer. The pressure when the radial pulse is no longer palpable is the estimated SBP. The cuff is then deflated rapidly.

Korotkoff sounds: The head of the stethoscope, ideally using the bell, should be placed over the brachial artery, with each earpiece in the clinician's ear. The cuff should then be rapidly inflated to 20–30 mm Hg above the estimated SBP from the palpatory method. The cuff is slowly deflated at a rate of 2 mm Hg/second while the clinician simultaneously listens for phase 1 (the first appearance of sounds) and phase 5 (the disappearance of sounds) Korotkoff sounds while also observing the manometer. When the pressure is 10–20 mm Hg below phase 5, the cuff can be rapidly deflated.

Documentation: BP values should always be recorded. The BP values (SBP/DBP) should be recorded using even numbers (rounded up from an odd number)[a] along with the patient's position (seated, standing, or supine), arm used, cuff size, time, and date.

Repeat: A second measurement should be taken after at least 1 minute in the same arm. If the readings differ by >5 mm Hg, additional measurements should be obtained. The mean of these values should be used to make clinical decisions. BP should be taken in both arms at the initial visit, with the BP measured in the arm with the higher reading at subsequent visits.

BP, blood pressure; DBP, diastolic blood pressure; SBP, systolic blood pressure.

[a]Terminal digit preference (ie, tendency to report readings that end in 0 or 5) should be avoided.

Correct BP measurements require that the clinician listen through a stethoscope that is placed over the brachial artery for the appearance of the five phases of the Korotkoff sounds. Each sound has distinct features, which are depicted in **Figure 9-1**.[7]

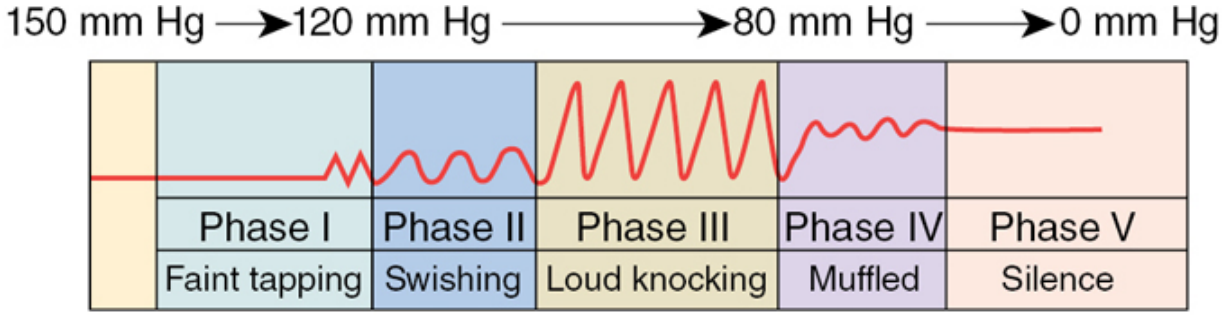

Figure 9-1 Phases of the Korotkoff sounds heard when indirectly measuring blood pressure. (Reprinted with permission from Timby BK. *Fundamental Nursing Skills and Concepts*. 11th ed. Wolters Kluwer; 2017.)

Out-of-office blood pressure monitoring

Home BP measurements can provide information on response to therapy and may help improve adherence to therapy and goal BP achievement in some patients.[8,9] Devices for home measurement should be validated for accuracy according to established protocols from either the British Hypertension Society or the Association for Advancement of Medical Instrumentation. When placed in service, they should be routinely checked against office-based readings for accuracy, especially when readings between office and home are widely discrepant. Patients with average home BP values >135/85 mm Hg are considered hypertensive.[8] Wrist or finger devices that measure BP are generally not accurate and should not be routinely used.

Ambulatory blood pressure monitoring (ABPM) typically measures BP every 15 to 30 minutes throughout the day and nighttime using a portable, noninvasive oscillometric device typically worn for 24 hours.[6] This form of specialized monitoring is indicated for patients with suspected white-coat hypertension and may also be helpful in patients with apparent drug resistance, hypotensive symptoms while receiving antihypertensive therapy, episodic hypertension, and autonomic dysfunction.[6] Similar to self-BP measurements, ABPM values are typically lower than office-based measurements. As a comparison, the normal upper limit for BP in most patients is 140/90 mm Hg for office-based measurement, 130/80 mm Hg for ABPM (135/85 mm Hg while awake and 120/75 mm Hg while asleep), and 135/85 mm Hg for self-BP measurements.[6] Therefore, the threshold for normal versus abnormal is lower than that obtained during office-based measurements.

Evidence indicates that ABPM recordings can predict clinical outcomes more strongly than do office-based BP measurements,

most likely because the device factors in BP throughout nighttime hours, which provides a more accurate reflection of the overall average pressure load.[10] However, in clinical practice, ABPM is not recommended for routine evaluation of responses to treatment for a number of reasons, including lack of widespread availability, cost, and intrusiveness of performing multiple ABPM sessions in the same patient.[6]

BP values measured outside the office should be considered in the overall treatment of patients with hypertension. However, it is important to acknowledge that office-based BP measurements have been the source used in the major clinical trials establishing that treatment of hypertension reduces morbidity and mortality rates. Therefore, they are still considered the standard values that should guide evaluation of response to antihypertensive drug therapy in most patients.

The reliability and accuracy of automated BP monitors, whether they are used in the office or out of the office, can vary significantly. For a summary of commercially available automatic monitors and whether they have passed validation protocols, refer to the dabl® Educational Trust website (http://www.dableducational.org). The use of BP measurements from automated machines commonly found in grocery stores and pharmacies may have questionable reliability. Measurements using these publicly available machines should not be relied on to make clinical decisions, but should be used to direct patients for follow-up with their medical provider as a screening tool.

Types of Hypertension

ESSENTIAL HYPERTENSION

Most patients with hypertension have essential hypertension (also known as primary hypertension), in which there is no identifiable cause for their chronically elevated BP.

SECONDARY HYPERTENSION

Patients with secondary hypertension have a specific identified cause for elevated BP (**Table 9-2**). Although only 5% to 10% of those among the hypertensive population have causes that are purely secondary, further diagnostic evaluation should occur if physical or laboratory findings suggest the possibility of a secondary cause (**Table 9-3**).[4,11,12] Some secondary causes are potentially reversible and may normalize BP (eg, coarctation of the aorta), whereas others are more often superimposed on and worsen an already elevated BP (eg, obstructive sleep apnea). The distinction is important because treatment of an underlying cause may not always be expected to completely normalize BP and allow discontinuation of antihypertensive therapies. In patients who have resistant hypertension (requiring three or more drugs for BP control) or who have a sudden and significant increase in BP, further diagnostic workup for secondary causes should be considered.

Table 9-2
Secondary Causes of Hypertension

Alcoholism
Chronic kidney disease
Chronic steroid therapy and Cushing syndrome
Coarctation of the aorta
Drug induced or drug related: • Amphetamines (amphetamine, dexmethylphenidate, dextroamphetamine, lisdexamfetamine, methylphenidate, phendimetrazine, and phentermine) • Antidepressants (bupropion, desvenlafaxine, and venlafaxine) • Antihypertensive agents that are abruptly stopped (only β-blockers and central α_2-agonists) • Anabolic steroids (eg, testosterone) • Calcineurin inhibitors (cyclosporine and tacrolimus) • Cocaine and other illicit drugs • Corticosteroids (cortisone, dexamethasone, fludrocortisone, hydrocortisone, methylprednisolone, prednisolone, prednisone, and triamcinolone) • Ephedra alkaloids • Erythropoiesis-stimulating agents (darbepoetin-α and erythropoietin) • Ergot alkaloids (ergonovine and methysergide)

• Estrogen-containing oral contraceptives (ethinyl estradiol) • Licorice (including some chewing tobacco) • Monoamine oxidase inhibitors (isocarboxazid, phenelzine, tranylcypromine sulfate) when given with tyramine-containing foods or with an interacting drug • Nonsteroidal anti-inflammatory drugs (all types) • Oral decongestants (eg, pseudoephedrine) • Phenylephrine (ocular administration) • Vascular endothelial growth factor inhibitor (bevacizumab) • Vascular endothelial growth factor receptor tyrosine kinase inhibitor (sorafenib and sunitinib)
Pheochromocytoma
Primary aldosteronism
Renovascular disease
Sleep apnea
Thyroid or parathyroid disease

Table 9-3
Clinical Findings Suggestive of Secondary Hypertension

Causes	Historical Findings	Physical Examination Findings	Laboratory Findings
Sleep apnea	Daytime fatigue and somnolence	Large neck circumference; overweight or obese	Abnormal sleep studies with frequent awakenings and anoxic episodes
Renovascular disease	Moderate or severe high BP before age 30 or after 55; rapidly progressive hypertension	Abdominal bruits; funduscopic hemorrhages	Suppressed or stimulated plasma renin activity; IVP (rapid sequence); digital subtraction angiography
Renoparenchymal disease	Dysuria, polyuria, nocturia; urinary tract infections; kidney stones; family history of polycystic or other types of kidney disease	Edema	Proteinuria; hematuria; bacteriuria
Coarctation of the aorta	Intermittent claudication	Diminished or absent femoral pulses compared with carotids; lower SBP in leg compared with arm	—
Pheochromocytoma	Paroxysmal headaches, palpitations, sweating, dizziness, and pallor	Nervousness, tremor, tachycardia, orthostatic hypotension	Clonidine suppression tests[a]; high urinary metanephrine or vanillylmandelic acid
Primary aldosteronism	Weakness, polyuria, polydipsia, intermittent paralysis	Orthostatic hypotension	Hypokalemia
Cushing syndrome	Menstrual irregularity	Moon face; truncal obesity; buffalo hump; hirsutism; violet striae	↑ serum glucose; ↑ plasma cortisol after suppression with dexamethasone

BP, blood pressure; IVP, intravenous pyelogram; SBP, systolic blood pressure.

[a]Failure of plasma catecholamines to ↓ by 50% within 3 hours of administration of 0.3 mg clonidine highly suggests pheochromocytoma.

WHITE-COAT HYPERTENSION

White-coat hypertension describes patients who have consistently elevated BP values measured in a clinical environment in the presence of a health care professional (eg, physician's office), yet when measured elsewhere or with 24-hour ambulatory monitoring, BP is not elevated.[6,7] Home BP monitoring or 24-hour ABPM is warranted in patients suspected of having white-coat hypertension to differentiate this from true hypertension.[6] The commonly used definition is a persistently elevated average office BP of >140/90 mm Hg and an average awake ambulatory reading of <135/85 mm Hg.[9] The label *white-coat hypertension* applies only to patients without target-organ disease who are not on antihypertensive therapy.

Significant controversies surround white-coat hypertension. Although this does not represent a clinical diagnosis, patients with white-coat hypertension are at risk for eventually developing essential hypertension. Moreover, patients with white-coat hypertension are at a higher risk for CV disease than are normotensive patients.[13] The decision to treat or not treat white-coat hypertension is controversial. Many patients enrolled in the landmark clinical trials that demonstrated reductions in CV morbidity and mortality with antihypertensive therapy likely had white-coat hypertension because only office BP measurements were used for inclusion. At minimum, patients with white-coat hypertension should be treated with lifestyle modifications and need to be closely monitored with a device that can measure BP outside the clinic environment if they are not treated with antihypertensive drug therapy.

HYPERTENSIVE CRISES

Hypertensive crises are situations in which measured BP values are markedly elevated (>180/110 mm Hg). They are classified as either a hypertensive emergency (with acute or progressive target-organ damage) or urgency (without acute or progressive target-organ

damage). Hypertensive emergencies require hospitalization for immediate BP lowering. Hypertensive urgencies do not require immediate BP lowering; instead, BP should be slowly reduced within 24 hours (but not generally to goal BP so quickly) (see Chapter 16, Hypertensive Crises).

Hypertension Management

Hypertension is treated with both lifestyle modifications and pharmacotherapy. As of today, the 2017 ACC/AHA Hypertension Treatment Guidelines are considered the "gold standard" consensus guidelines for the management of hypertension in the United States.[3] The overall principle is to implement lifestyle modifications in addition to pharmacotherapy to control BP in patients with general hypertension. In addition, the 2017 ACC/AHA Guidelines also focus on the presence of specific comorbidities in patients with hypertension and selection of specific pharmacotherapy for these patients. These issues are discussed later in this chapter.

GOALS

The overarching goal of treating patients with hypertension is to reduce associated morbidity and mortality. These manifest as hypertension-associated complications (**Table 9-4**), which include atherosclerotic vascular disease and other forms of CV disease.

Table 9-4
Hypertension-Associated Complications and Major Cardiovascular Risk Factors

Hypertension-Associated Complications
• Atherosclerotic vascular disease • Coronary artery disease (sometimes called coronary heart disease) • Myocardial infarction • Acute coronary syndromes • Chronic stable angina • Carotid artery disease

- Ischemic stroke
- Transient ischemic attack
- Peripheral arterial disease
- Abdominal aortic aneurysm
- Other forms of CV disease
- Left ventricular dysfunction (systolic heart failure)
- Chronic kidney disease
- Retinopathy

Major CV Risk Factors

- Advanced age (older than 55 years for males, older than 65 years for females)
- Cigarette smoking
- Diabetes mellitus
- Dyslipidemia
- Family history of premature atherosclerotic vascular disease (males younger than 55 years or females younger than 65 years) in primary relatives
- Hypertension
- Kidney disease (microalbuminuria or estimated GFR <60 mL/min/1.73 m^2)
- Obesity (BMI ≥ 30 kg/m^2)
- Physical inactivity

BMI, body mass index; CV, cardiovascular; GFR, glomerular filtration rate.

Goal blood pressure values

Achieving goal BP is an important step in the overall treatment of patients with hypertension. According to the 2017 ACC/AHA Hypertension Treatment Guidelines, patients older than 18 years with hypertension and atherosclerotic cardiovascular disease (ASCVD) risk ≤10% should have a BP threshold of 140/90 mm Hg to initiate pharmacologic therapy.[3] For those with CV risk factors and comorbidities and ASCVD risk >10%, the BP threshold for initiation of pharmacologic therapy is 130/80 mm Hg.

The issue of whether more aggressive BP goals (ie, <130/80 or <120/80 mm Hg) result in better reductions in risk of CV events than does the standard goal of <140/90 mm Hg for patients with ASCVD risk ≥10% over the year has been through some controversies, especially in some patient populations such as the elderly and patients with diabetes or CKD.

In elderly patients, moderate-quality earlier evidence from three trials (Systolic Hypertension in the Elderly Program [SHEP], Syst-Eur, and the UK Prospective Diabetes Study Group [UKPDS]) has shown that treatment of hypertension to an SBP goal of <150 mm Hg improves CV and cerebrovascular health outcomes and lowers mortality in adults with diabetes and hypertension.[14–16] However, within this population, the only clear prospective data supporting the benefits of antihypertensive therapy is from the Hypertension in the Very Elderly Trial (HYVET), which used a BP goal of <150/80 mm Hg.[17] It is important to note that BP goals among the elderly have always been based primarily on expert consensus. The BP treatment goal for individual elderly patients, to a certain extent, should be determined by their frailty and their ability to tolerate side effects of antihypertensive agents (such as orthostatic hypotension).

In patients with diabetes, an earlier recommendation for an SBP goal was <140 mm Hg. This was supported by the Action to Control Cardiovascular Risk in Diabetes–Blood Pressure (ACCORD BP) trial, which demonstrated[18] no difference in the primary end point of major CV events when patients with type 2 diabetes were treated to an SBP goal of <120 mm Hg compared with an SBP goal of <120 mm Hg after a mean of 4.7 years.

Similarly, in patients with CKD, earlier evidence of moderate quality demonstrating no benefit in slowing the progression of kidney disease from treatment with antihypertensive drug therapy to a lower BP goal (eg, <130/80 mm Hg) compared with a goal of <140/90 mm Hg.[19–21]

However, in 2015, the publication of the results of the Systolic Blood Pressure Intervention Trial (SPRINT) changed some of these perspectives. SPRINT is a randomized, multicenter clinical trial that compares intensive hypertension treatment (SBP goal <120 mm Hg) with standard treatment (SBP goal <140 mm Hg) in 9361 patients with hypertension and at least one other CV risk factor (patients with a history of diabetes or stroke are excluded). At 1 year, the mean SBP was 121.4 mm Hg in the intensive treatment group and 136.2 mm Hg in the standard treatment group. The intervention was stopped early after a median follow-up of 3.26 years owing to a

significantly lower rate of the primary composite outcome (myocardial infarction [MI], acute coronary syndrome [ACS] not resulting in MI, stroke, acute decompensated heart failure, or death from CV causes) in the intensive treatment group than in the standard treatment group (1.65% vs 2.19% per year; $P < .001$).[22] Based on the result of the SPRINT trial, in 2017, the ACC and AHA collaborated with the NHLBI and stakeholder and professional organizations to publish a new hypertension treatment guideline, addressing treatment goals for patients with hypertension and at least one other CV risk factor or other CV comorbidity (including the elderly and CKD).[3] Some of these CV risk factors and comorbidities are discussed in more detail later in this chapter. In this guideline, it is recommended that except patients who have 10 years' ASCVD risk <10%, all other patients should have a BP treatment goal of <130/80 mm Hg. Patients with ASCVD risk <10% can have a pharmacologic treatment threshold of >140/90 mm Hg (https://tools.acc.org/ascvd-risk-estimator-plus/#!/calculate/estimate/). When their BP is between 130/80 and 140/90 mm Hg, they can be managed with nonpharmacologic management alone.

LIFESTYLE MODIFICATIONS

Lifestyle modifications are the cornerstone of management for preventing and treating hypertension. AHA guidelines for lifestyle modifications recommend both diet and exercise.[23,24] These recommendations are summarized in **Table 9-5**. Engaging in these modifications is encouraged for all persons to prevent the development of hypertension; however, they are recommended as a component of first-line therapy in all patients with prehypertension and in all patients with a diagnosis of hypertension regardless of whether their BP values are at goal or not.[2,3] Independent of BP lowering, CV risk may also be reduced.

Table 9-5
Lifestyle Modifications to Prevent and Treat Hypertension

Lifestyle Modification	Recommendations
Weight management	Approximately 1 mm Hg for every 1 kg reduction in body weight
DASH diet	Consume diet rich in fruits, vegetable, whole grains, low-fat dairy, with reduced saturated or total fat
Sodium restriction	<1500 mg/day
Potassium intake	3500–5000 mg/day
Physical exercise	Aerobic exercise 90–150 minutes/week
Alcohol consumption	Males ≤2 drinks daily; Females ≤1 drink daily[a]

DASH, dietary approaches to stop hypertension.

[a]One drink contains ~14 g of pure alcohol [12 oz of regular beer (usually about 5% alcohol), 5 oz of wine (usually about 12% alcohol), and 1.5 oz of distilled spirits (usually about 40% alcohol)].

Weight reduction

Weight loss as small as 5% to 10% of body weight in overweight individuals may significantly lower CV risk. For most patients, an average weight loss of 22.04 pounds (10 kg) can reduce SBP by 5 to 20 mm Hg, a reduction comparable to that achieved from the addition of an antihypertensive drug used as monotherapy.[2,3]

DASH eating plan

The DASH (Dietary Approaches to Stop Hypertension) diet is rich in fruits, vegetables, and low-fat dairy foods, coupled with reduced saturated and total fat.[25] The patient education publication entitled "Your Guide to Lowering Your Blood Pressure With DASH" can be found at https://www.nhlbi.nih.gov/files/docs/public/heart/new_dash.pdf. The DASH diet can substantially reduce BP (8–14 mm Hg in SBP for most patients) and yield results similar to that of single-drug therapy. The low-fat component of this diet is important because weight loss

is more readily achieved by a reduced-calorie diet (fats contribute more calories per gram than do either carbohydrates or protein) and lowered fat intake also reduces the risk of CV disease by lowering cholesterol.

Dietary sodium restriction

The average intake of sodium in the United States is >6 g/day. Restricting sodium should be encouraged in patients with prehypertension or hypertension, and the current recommendation to restrict daily sodium intake to ≤1.5 g is lower than what has traditionally been suggested. Some clinicians may argue that the efficacy of implementing sodium restriction in patients with hypertension may vary. Evidence from clinical trials has shown, however, that sodium restriction provides mean reductions in BP of 5/2.7 mm Hg in patients with hypertension.[25] Restricting sodium to <1.5 g daily has been shown to decrease SBP by >20 mm Hg in patients with resistant hypertension.[26] Some populations (patients with diabetes and Black and elderly patients) respond better to sodium restriction than do the general population, but all patients with hypertension should be instructed to reduce their sodium intake. They should be counseled not to add salt to foods and to avoid or minimize ingestion of processed or packaged foods, foods with high sodium content, and nonprescription drugs containing sodium.

Increased potassium intake

Increasing dietary potassium intake is recommended, although it is not commonly identified by most patients as a dietary modification that will lower BP. Adhering to a DASH eating plan will usually assure an intake of the recommended 4.7 g daily. Dietary supplementation should be the primary strategy to increase potassium. Implementing potassium supplementation outside of dietary sources for the sole purpose of lowering BP should be avoided because of the potential harm from hyperkalemia. Moreover, potassium supplementation in patients with hypertension who are treated with a potassium-sparing diuretic, aldosterone antagonist,

angiotensin-converting enzyme inhibitor (ACEI), or an angiotensin-receptor blocker (ARB) may cause hyperkalemia. This can also occur in patients with hypertension and CKD who are treated with potassium supplementation.

Moderate alcohol consumption

Explaining the need to limit alcohol consumption is complicated. Although data suggest that small daily doses of alcohol (eg, one glass of red wine with dinner) are associated with lower CV risk, excessive alcohol intake can elevate BP, decrease the effectiveness of antihypertensive medications, and increase the risk of stroke. Patients who consume three to four drinks per day experience a 3 to 4 mm Hg increase in SBP and a 1 to 2 mm Hg increase in DBP compared with those who do not drink. These increases are even higher in patients who consume more alcohol. Moderate alcohol consumption of two or fewer drinks daily in males and one or fewer drinks daily in females or lighter weight individuals can decrease SBP approximately 2 to 4 mm Hg. Patients should be instructed that one drink is equal to 1.5 oz of 80-proof whiskey, 5 oz of wine, or 12 oz of beer.

Physical activity

Regular physical activity can reduce SBP by 4 to 9 mm Hg in most patients.[2,3] Benefits include reducing the incidence of hypertension, assisting weight loss and weight loss maintenance, and improving overall CV fitness. Most patients with hypertension can safely increase their regular aerobic activity. Those with more severe forms of target-organ damage (eg, angina and previous MI) may, however, need a medical evaluation before increasing their activity level. Physical activity should ideally occur for at least 30 minutes, at least 5 days of the week, but preferably daily. Walking, running, cycling, swimming, and cross-country skiing are examples of aerobic exercise that are recommended for physical activity.

PHARMACOTHERAPY

Numerous clinical trials have demonstrated that antihypertensive pharmacotherapy reduces the risk of hypertension-associated complications (eg, CV morbidity and mortality). The ACC/AHA Hypertension Guidelines recommend that in the general non-Black population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic, calcium channel blocker (CCB), ACEI, or ARB. In the general Black population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic or CCB. In the population older than 18 years with CKD, initial (or add-on) antihypertensive treatment should include an ACEI or ARB to improve kidney outcomes. This applies to all patients with CKD having hypertension regardless of race or diabetes status. Evidence obtained since the 2003 JNC-7 guidelines demonstrates that, for first-line treatment in primary prevention patients, β-blocker therapy is not as effective in reducing CV events compared with ACEI, ARB, CCB, or thiazide diuretic therapy.[27] Therefore, unlike previous versions of the JNC Hypertension Treatment Guidelines, β-blocker is no longer recommended as one of the first-line treatment options, unless comorbidities such as MI and heart failure require them to receive β-blocker therapy. Moreover, newer evidence also suggests that the reductions in CV events with ACEI, ARB, CCB, or thiazide diuretic are comparable, so that one agent is not automatically preferred over another.[26]

First-line agents

Angiotensin-Converting Enzyme Inhibitors

The ACEIs directly inhibit ACE, blocking the conversion of angiotensin I to angiotensin II. This action reduces angiotensin II–mediated vasoconstriction and aldosterone secretion and ultimately lowers BP. Because additional pathways exist for the formation of angiotensin II, ACEIs do not completely block the production of angiotensin II. Aldosterone release is indirectly suppressed by ACEIs; thus, hyperkalemia is possible and potassium concentrations should be monitored. Patients with CKD or volume depletion may be

more susceptible to hyperkalemia or to further kidney dysfunction owing to a higher dependence on the vasoconstriction provided by angiotensin II to support glomerular filtration rate (GFR) among these patients.

Inhibiting ACE also prevents the breakdown and inactivation of bradykinin, which may lead to additive vasodilation by enhancing NO. However, bradykinin accumulation can also cause a nonproductive cough in some patients, which is the most frequent, yet harmless, side effect of ACEI therapy. ACEI therapy has been associated with angioedema, which is a rare, but serious, hypersensitivity reaction. Angioedema typically presents as swelling of the tongue, lips, and mouth, but it can also involve the eyes and upper airway.

The development of angioedema requires discontinuation of the ACEI. These agents are metabolically neutral and may have a positive effect on insulin resistance and risk of progression to type 2 diabetes.[28]

Angiotensin-Receptor Blockers

The ARBs modulate the RAAS by directly blocking the angiotensin II type 1 receptor site, preventing angiotensin II–mediated vasoconstriction and aldosterone release. Overall, ARBs are the best tolerated of the first-line agents.[29] They do not affect bradykinin and are therefore associated with less incidence of cough. Because aldosterone is indirectly suppressed, monitoring of potassium is important to avoid hyperkalemia. Similar to the ACEIs, patients with CKD or volume depletion may be more susceptible to hyperkalemia or to further kidney dysfunction. These agents are metabolically neutral and may have a positive effect on insulin resistance and risk of progression to type 2 diabetes.[28]

Calcium Channel Blockers

The CCBs are pharmacologically complex. They reduce calcium entry into smooth muscles, which causes coronary and peripheral vasodilation and lowers BP. All decrease cardiac contractility (except

amlodipine and felodipine). Dihydropyridine CCBs are primarily vasodilators that can cause a reflex tachycardia. This is in contrast to the nondihydropyridine CCBs (verapamil and diltiazem) that directly block the atrioventricular (AV) node, decrease heart rate, and decrease cardiac contraction, yet have vasodilatory effects. Side effects depend on the type of CCB, but can include flushing, peripheral edema, tachycardia, bradycardia or heart block, and constipation.

Thiazide Diuretics

Diuretics, particularly thiazide and thiazide-like (eg, chlorthalidone) diuretics, have been extensively studied in large landmark clinical trials for hypertension. When initially started, they induce a natriuresis that causes diuresis and decreases plasma volume and CO. With chronic use, diuresis usually dissipates, and CO gradually returns to near-normal levels. The long-term BP-lowering effect in the face of these changes suggests a sustained decrease in PVR as the primary mechanism responsible.

Dose-related electrolyte and metabolic alterations (eg, hypokalemia, hyperuricemia, hyperglycemia, and hypercholesterolemia) can occur with thiazide diuretics. These effects were particularly problematic when high doses were used many years ago (eg, hydrochlorothiazide [HCTZ] 100–200 mg/day), but are drastically minimized using lower doses that are now considered the standard of care (eg, HCTZ 12.5–25 mg/day).[30] Thiazide diuretics can be used in combination with a potassium-sparing diuretic (ie, triamterene and amiloride) to minimize potential potassium depletion. Other biochemical changes in glucose and cholesterol are minimal and mostly transient with low-dose therapy.

Second-line agents

β-Blockers

β-Blockers have several direct effects on the CV system. They can decrease cardiac contractility and CO, lower heart rate, blunt sympathetic reflex with exercise, reduce central release of

adrenergic substances, inhibit norepinephrine release peripherally, and decrease renin release from the kidney. All these contribute to their antihypertensive effects. Adverse metabolic effects include altered lipids and increased glucose concentrations. Similar to thiazide diuretics, these changes are generally temporary and have minimal to no clinical significance. These agents were considered first line for the treatment of most patients with hypertension in previous hypertension treatment guidelines. However, more recent treatment has further defined their role.[27] Unless patients have other indication for β-blockers (eg, coronary artery disease [CAD] or left ventricular dysfunction), they should not be used as a first-line agent for primary prevention of CV events in patients with hypertension.

Aldosterone Antagonists

Spironolactone and eplerenone are aldosterone antagonists. Potent blockade of the aldosterone receptor inhibits sodium and water retention and inhibits vasoconstriction. These agents are also considered potassium-sparing diuretics. Hyperkalemia is a known dose-dependent effect with aldosterone antagonists and is more prominent in patients with CKD or in patients taking a concurrent RAAS blocking agent (ACEI, ARB, or direct renin inhibitor). Gynecomastia is a side effect of spironolactone, usually more common with higher doses, that does not occur with eplerenone.

Other agents

There are other antihypertensive drug classes, many of which are older agents, which should primarily be used to provide additional BP lowering only after first-line and second-line agents have been implemented.

Loop diuretics (eg, furosemide and torsemide) can be used in some patients for hypertension.[30] When dosed appropriately; they can provide BP reductions similar to those seen with a thiazide diuretic. Because they are short acting and subject to a significant postdose antinatriuretic effect, they should generally be reserved for patients with heart failure or severe CKD in whom their diuretic

action remains prolonged. Significant edema usually accompanies these conditions, such that they generally require a loop diuretic instead of a thiazide diuretic for adequate diuresis and volume removal. Because they are more potent at inducing diuresis compared with thiazide diuretics, they can cause more electrolyte disturbances (eg, hypokalemia).

Aliskiren is the only direct renin inhibitor. Similar to an ACEI or ARB, this agent is a RAAS blocker. It is approved for treatment of hypertension and has been studied in combination with an ACEI, ARB, or a thiazide diuretic. It is the newest antihypertensive drug class; therefore, its exact role will continue to evolve as additional clinical data are generated.

α-Blockers (eg, doxazosin, prazosin, and terazosin) attach to peripheral α_1-receptors, inhibiting the uptake of catecholamines in smooth muscle, and cause vasodilation. Although effective in lowering BP, they have more side effects than first-line or second-line agents. The most prominent side effect is hypotension, which is most evident after the first dose and with postural changes (arising from a lying position to a standing position).

Direct vasodilators (eg, hydralazine and minoxidil) work on the arterial vasculature. They should be reserved for patients with specific conditions (eg, severe CKD) or those with very difficult to control BP. Concomitant drug therapy with both a diuretic and an agent that lowers heart rate (a β-blocker, diltiazem, or verapamil) is usually needed to mitigate the associated fluid retention and reflex tachycardia that frequently occur.

Central α_2-agonists (eg, clonidine and methyldopa) work in the vasomotor centers of the brain where they stimulate inhibitory neurons and decrease sympathetic outflow from the CNS. The resultant decrease in PVR and CO lowers BP. These agents commonly cause anticholinergic side effects (eg, sedation, dizziness, dry mouth, and fatigue) and possibly sexual dysfunction. Although α_2-agonists lower BP, they often cause fluid retention and should be used in combination with a diuretic.

CLINICAL EVALUATION

Patient Presentation

CASE 9-1

QUESTION 1: D.C. is a 44-year-old Black male who presents to his primary care provider concerned about high BP. At an employee health screening last month, he was told he had hypertension. His medical history is significant for allergic rhinitis. His BP was 144/84 and 146/86 mm Hg last year during an employee health screening at work. D.C.'s father had hypertension and died of an MI at age 54. His mother had diabetes and hypertension and died of a stroke at age 68. D.C. smokes one pack per day of cigarettes and thinks his BP is high because of job-related stress. He does not believe that he really has hypertension. D.C. does not engage in any regular exercise and does not restrict his diet in any way, although he knows he should lose weight.

Physical examination shows he is 68.89 inches (175 cm) tall, weighs 238.09 pounds (108 kg) (body mass index [BMI] 35.2 kg/m^2), BP is 148/88 mm Hg (left arm) and 156/86 mm Hg (right arm) while sitting, and heart rate is 80 beats/min. Six months ago, his BP values were 152/88 and 160/84 mm Hg when he was seen by his primary care provider for allergic rhinitis. Funduscopic examination reveals mild arterial narrowing and arteriovenous nicking, with no exudates or hemorrhages. The other physical examination findings are essentially normal.

D.C.'s fasting laboratory serum values are as follows:
Blood urea nitrogen (BUN), 24 mg/dL
Creatinine, 1.0 mg/dL
Glucose, 105 mg/dL
Potassium, 4.4 mEq/L
Uric acid, 6.5 mg/dL
Total cholesterol, 196 mg/dL
Low-density lipoprotein cholesterol (LDL-C), 141 mg/dL
High-density lipoprotein cholesterol (HDL-C), 32 mg/dL
Triglycerides, 170 mg/dL

An electrocardiogram (ECG) is normal except for left ventricular hypertrophy (LVH).

Why does D.C. have hypertension?

D.C. has hypertension. He has had elevated BP values, measured in clinical environments, and meets the diagnostic criteria for

hypertension because two or more of his BP measurements are elevated on separate days.

Case 9-1, Question 2: What is the proper assessment of D.C.'s BP?

D.C. has essential hypertension; therefore, the exact cause is not known. He has several characteristics (eg, family history of hypertension and obesity) that may have increased his chance of developing hypertension. Race and sex also influence the prevalence of hypertension. Across all age groups, Blacks have a higher prevalence of hypertension than do Whites and Hispanics.[1] Similar to other forms of CV disease, hypertension is more severe, more likely to include hypertension-associated complications, and occurs at an earlier age in Black patients.

Patient Evaluation and Risk Assessment

The presence or absence of hypertension-associated complications as well as other major CV risk factors (Table 9-4) must be assessed in D.C. Also, secondary causes of hypertension (Table 9-2), if suggested by history and clinical examination findings, should be identified and managed accordingly. The presence of concomitant medical conditions (eg, diabetes) should be assessed, and lifestyle habits should be evaluated so that they can be used to guide therapy.

HYPERTENSION-ASSOCIATED COMPLICATIONS

Case 9-1, Question 3: Which hypertension-associated complications are present in D.C.?

A complete physical examination to evaluate hypertension-associated complications includes examination of the optic fundi; auscultation for carotid, abdominal, and femoral bruits; palpation of the thyroid gland; heart and lung examination; abdominal

examination for enlarged kidney, masses, and abnormal aortic pulsation; lower extremity palpation for edema and pulses; and neurologic assessment. Routine laboratory assessment after diagnosis should include the following: ECG; urinalysis; fasting glucose; hematocrit; serum potassium, creatinine, and calcium; and a fasting lipid panel. Optional testing may include measurement of urinary albumin excretion or albumin-to-creatinine ratio, or additional tests specific for secondary causes if suspected.

D.C. does not yet have hypertension-associated complications. He is exhibiting early signs, however, based on his physical examination that, if left untreated, will likely develop into such complications. These early signs have likely evolved from his long-standing, poorly controlled hypertension. D.C.'s ECG revealed LVH, indicating early cardiac damage. Although the gold standard for confirming LVH is echocardiography, this confirmatory procedure is not necessary unless symptoms are present indicating that LVH has progressed to left ventricular dysfunction (eg, peripheral edema and shortness of breath). His funduscopic examination reveals mild arterial narrowing and arteriovenous nicking, which are early signs of retinopathy and atherosclerosis. D.C.'s serum creatinine is normal, ruling out overt CKD. Additional testing for microalbuminuria is needed, however, to confirm that he does not have early-stage kidney disease.

CASE 9-1, QUESTION 4: What other forms of hypertension-associated complications is D.C. at risk for?

Hypertension adversely affects many organ systems, including the heart, brain, kidneys, peripheral circulation, and eyes. These are summarized in Table 9-4. Damage to these systems resulting from hypertension is termed *hypertension-associated complications*, *target-organ damage*, or *CV disease.* There are often misconceptions about the terms CV disease and CAD. CV disease encompasses the broad scope of all forms of hypertension-associated complications. CAD is simply a subset of CV disease and refers specifically to disease related to the coronary vasculature,

including ischemic heart disease and MI. Hypertension-associated complications and major risk factors for developing such complications should be assessed by a thorough patient history, a complete physical examination, and laboratory evaluation.

Hypertension can affect the heart either indirectly, by promoting atherosclerotic changes, or directly, via pressure-related effects. Hypertension can promote CV disease and increase the risk of *ischemic events*, such as angina and MI. Antihypertensive therapy has been shown to reduce the risk of these coronary events. Hypertension also promotes the development of LVH, which is a myocardial (cellular) change, not an arterial change. However, these two conditions often coexist. It is commonly believed that LVH is a compensatory mechanism of the heart in response to the increased resistance caused by elevated BP. LVH is a strong and independent risk factor for CAD, left ventricular dysfunction, and arrhythmia. LVH does not indicate the presence of left ventricular dysfunction, but it is a risk for progression to left ventricular dysfunction, which is considered a hypertension-associated complication. This may be caused by ischemia, excessive LVH, or pressure overload. Ultimately, left ventricular dysfunction results in a decreased ability to contract (systolic dysfunction).

Hypertension is one of the most frequent causes of cerebrovascular disease. Cerebrovascular signs can manifest as transient ischemic attacks, ischemic strokes, multiple cerebral infarcts, and hemorrhages. Residual functional deficits caused by stroke are among the most devastating forms of hypertension-associated complications. Clinical trials have demonstrated that antihypertensive therapy can significantly reduce the risk of both initial and recurrent stroke. A sudden, prolonged increase in BP can also cause hypertensive encephalopathy, which is classified as a hypertensive emergency.

The GFR is used to estimate kidney function, which declines with aging. This rate of decline is greatly accelerated by hypertension. Hypertension is associated with nephrosclerosis, which is caused by increased intraglomerular pressure. CKD, whether mild or severe, can progress to kidney failure (stage 5 CKD) and the need for

dialysis. Studies have demonstrated that controlling hypertension is the most important strategy to slow the rate of kidney function decline,[31] but it may not be entirely effective in slowing the progression of renal impairment in all patients.

CKD is staged based on estimated glomerular filtration rate (eGFR) values.[32] Stage 3 CKD (moderate) is defined as an eGFR 30 to 59 mL/min/1.73 m^2, stage 4 CKD (severe) is 15 to 29 mL/min/1.73 m^2, and stage 5 (kidney failure) is <15 mL/min/1.73 m^2 or the requirement of dialysis. In hypertension, stage 3 CKD or worse is considered a hypertension-associated complication. An eGFR of <60 mL/min/1.73 m^2 corresponds approximately to a serum creatinine concentration of >1.5 mg/dL in an average male and >1.3 mg/dL in an average female. The presence of persistent albuminuria (>300 mg albumin in a 24-hour urine collection or 200 mg albumin/g creatinine on a spot urine measurement) also indicates significant CKD. (Note: These definitions of the stages of kidney disease and albuminuria will be used throughout the remaining cases in this chapter.) Assessment of kidney function is discussed in Chapter 2, Interpretation of Clinical Laboratory Tests, and Chapter 28, Chronic Kidney Disease.

Peripheral arterial disease, a noncoronary form of atherosclerotic vascular disease, is considered a hypertension-associated complication. It is equivalent in CV risk for CHD.[4] Risk factor reduction, BP control, and antiplatelet agent(s) are needed to decrease progression. Complications of peripheral arterial disease can include infection and necrosis, which in some cases require revascularization procedures or extremity amputation.

Hypertension causes retinopathies that can progress to blindness. Retinopathy is evaluated according to the Keith, Wagener, and Barker funduscopic classification system. Grade 1 is characterized by narrowing of the arterial diameter, indicating vasoconstriction. Arteriovenous nicking is the hallmark of grade 2, indicating atherosclerosis. Long-standing, untreated hypertension can cause cotton wool exudates and flame hemorrhages (grade 3). In severe cases (eg, hypertensive emergency), papilledema occurs, and this is classified as grade 4.

MAJOR RISK FACTORS

CASE 9-1, QUESTION 5: Which major CV risk factors are present in D.C.?

Hypertension is one of nine major CV risk factors (Table 9-4). These are not risk factors for developing hypertension; rather, they increase the risk of hypertension-associated complications. D.C. has multiple CV risk factors: smoking, dyslipidemia, family history of premature coronary heart disease (CHD) in a first-degree relative (father), hypertension, obesity, and physical inactivity.

D.C. is a primary prevention patient because he does not yet have any hypertension-associated complications. He has multiple major CV risk factors, so controlling his BP is of paramount importance to reduce the risk of developing hypertension-associated complications.

Many of D.C.'s risk factors are modifiable. He is a smoker, and this significantly increases his CV risk and may reduce the efficacy of antihypertensive therapy. Smoking cessation may not independently lower D.C.'s BP, but it will decrease his overall risk of CV disease (see Chapter 91, Tobacco Use and Dependence). D.C. is obese, based on his BMI. His lack of physical activity and dietary patterns have likely contributed to his obesity. A more focused patient interview on diet and exercise would be helpful to reinforce the assumption that he has a sedentary lifestyle. D.C.'s dyslipidemia increases his CV risk, and lipid-lowering therapy should be considered to further decrease the risk of CV disease (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).[33]

Advanced age is considered a major CV risk factor. Although CHD in the elderly is not considered premature, increasing age increases the risk of hypertension-associated complications. Premenopausal females are at low risk for CV disease. However, CV risk in females increases significantly after menopause, similar to the increased risk in males. Therefore, cutoff values for age as a risk factor in males and females are separated by 10 years (>55 years for males, >65 years for females). At age 50, D.C. does not yet have this risk factor.

Case 9-1, Question 6: What is D.C.'s BP goal?

The overarching goal of treating hypertension is to lower hypertension-associated complications. Control of BP is the most feasible clinical end point to guide therapy and should be viewed as a surrogate for attaining this goal. D.C.'s goal BP is <130/80 mm Hg, according to the 2017 ACC/AHA Hypertension Guidelines. His calculated ASCVD goal is ~11%. The presence of LVH reflects subclinical CV disease, according to the SPRINT study.[22]

PRINCIPLES OF TREATMENT

Goals of Therapy

Case 9-1, Question 7: What are the goals of treating D.C.?

Pharmacotherapy principles to achieve these goals include selecting a treatment regimen with antihypertensive agent(s) that reduces risk of CV events, complemented by appropriate lifestyle modifications (Table 9-5).

Health Beliefs and Patient Education

Case 9-1, Question 8: What patient education should be provided to D.C. regarding his hypertension?

Patient education is needed to ensure that D.C. understands his disease and its complications (**Table 9-6**). This should comprehensively include information on disease, treatment, adherence, and complications. Several approaches can be effective, but all methods should include direct communication between the clinician and the patient. Multidisciplinary approaches to disease-

state management in hypertension can effectively use a team of different clinicians (eg, physicians, nurse practitioners, physician assistants, and pharmacists). Providing face-to-face education is most common, but the key components in patient education can be delivered via indirect interactions (eg, telephone).

Table 9-6

Patient–Provider Interactions for Hypertension

Patient Education

- Assess patient's understanding and acceptance of the diagnosis of hypertension.
- Discuss patient's concerns and clarify misunderstandings.
- When measuring BP, inform the patient of the reading both verbally and in writing.
- Assure patient understands his or her goal BP value.
- Ask patient to rate (1–10) his or her chance of staying on treatment.
- Inform patient about recommended treatment, including lifestyle modification. Provide specific written information using standard brochures when available.
- Elicit concerns and questions and provide opportunities for patient to state specific behaviors to carry out treatment recommendations.
- Emphasize
  - the need to continue treatment.
  - that control does not mean cure.
  - that elevated BP is usually not accompanied by symptoms.

Individualize Treatment Regimens

- Include the patient in decision-making.
- Simplify the regimen to once-daily dosing, whenever possible.
- Incorporate treatment into patient's daily lifestyle.
- Set realistic short-term objectives for specific components of the medication and lifestyle modification plan.
- Encourage discussion of diet and physical activity, adverse drug effects, and concerns.
- Encourage self-monitoring with validated BP devices.
- Minimize the cost of therapy, when possible.
- Discuss adherence at each clinical encounter.
- Encourage gradual sustained weight loss.

BP, blood pressure.

Education should be tailored to the patient's specific needs. For example, some patients are able to comprehend the importance of achieving controlled BP by reading written materials, whereas others understand this only after implementing self-BP monitoring. The patient education process must be continuous throughout the duration of therapy. Not all aspects need to be discussed during each clinical interaction. Careful selection of both written and verbal information should be considered so that patients are not overwhelmed or intimidated. The NHLBI patient education materials are available at http://www.nhlbi.nih.gov/health/public/heart/index.htm#hbp. It is important that clinicians review all materials provided to patients to identify the source of information, assess ease of reading, and identify omitted information and sources of confusion or anxiety (eg, drug side effects).

Patients such as D.C. often incorrectly explain BP elevation as stress related. Although certain patients (eg, those with white-coat hypertension) may have BP that is more highly reactive, most patients with essential hypertension will have an elevated BP regardless of their stress level. D.C. should be informed about the cause of his disease and the lack of correlation between stress or symptoms and high BP. Importantly, D.C. needs to realize that elevated BP is almost always asymptomatic and that it can cause serious long-term complications. It is essential that he understands the chronic nature of hypertension and the need for long-term therapy. Otherwise, he may adhere to his treatment only when he "feels his BP is high" or during stressful events.

Some patients believe they can control their BP by stress management rather than with antihypertensive drug therapy and lifestyle modifications. Controlled trials have not consistently proved that stress management is beneficial in treating hypertension.[34] It is important to determine the patient's health beliefs and attitudes and to provide education about the etiology and management of hypertension to promote BP control.

Another common myth patients believe is that treating hypertension commonly leads to fatigue, lethargy, and sexual

dysfunction. This misconception can compromise adherence and be a limiting factor in appropriate management. Clinical trials have repeatedly reported that quality of life is better with active medication than with placebo.[35–38] Data have indicated that as many as 27% of males with hypertension have erectile dysfunction.[7] Although many patients believe this to be a medication-related side effect and that incidence rates vary among antihypertensive agents and classes, erectile dysfunction is likely caused by penile arterial changes (probably atherosclerosis), which is related to uncontrolled or untreated hypertension.[39]

Benefits of Treatment

Case 9-1, Question 9: How can antihypertensive drug therapy reduce D.C.'s risk of hypertension-associated complications?

Without a doubt, antihypertensive therapy reduces the risk of CV disease and CV events in patients with hypertension. Numerous landmark placebo-controlled studies have clearly demonstrated these benefits. The first large-scale trial, published in 1967, was the Veterans Administration (VA) study in males with DBP between 115 and 129 mm Hg.[40] This study was prematurely stopped because benefits of treatment were so dramatic. Antihypertensive therapy significantly reduced cerebral hemorrhage, MI, left ventricular dysfunction, retinopathy, and kidney disease. Other landmark placebo-controlled studies have evaluated antihypertensive therapy in patients with less severe hypertension and have shown a reduced risk of CV events (stroke, ischemic heart disease, and left ventricular dysfunction) and even CV death.[31,32,41,42] Placebo-controlled studies evaluating morbidity and mortality in hypertension are now not only unnecessary but also considered unethical because of the well-established benefits of treatment. Even small reductions in BP have been associated with significant CV benefits. Based on prospective observational studies, a persistent 5 mm Hg reduction in DBP is

associated with a 21% reduction in CHD and a 34% reduction in stroke.[43,44]

Most antihypertensive drugs reduce LVH through varying mechanisms. It is logical that regression of LVH is desirable, but this remains unproved.

Case 9-1, Question 10: Will D.C.'s early signs of hypertension-associated complications improve or reverse with appropriate BP control?

Reductions in BP can reverse many of the changes associated with D.C.'s retinopathy. Studies have demonstrated that the risk of retinopathy in diabetes increases significantly when BP is elevated and that BP lowering can slow this progression. Although D.C. has an elevated fasting glucose, he does not have diabetes. Regardless, lowering BP is desirable for anticipated beneficial effects on his retinopathy.

HYPERTENSION MANAGEMENT

Lifestyle Modifications

Case 9-1, Question 11: Should D.C. start antihypertensive drug therapy, or are lifestyle modifications alone sufficient?

It is reasonable to assume that lifestyle modifications can partially help D.C. achieve his BP goal. D.C. has multiple major CV risk factors and has early evidence of hypertension-associated complications. Lifestyle modifications are germane to the appropriate treatment of hypertension, but prospective clinical trials have not proved that this treatment approach prevents CV disease in patients with hypertension similar to what is proven antihypertensive drug therapy. Hence, initiation of drug therapy should not be delayed unnecessarily, especially for patients with CV risk factors.

MODALITIES THAT LOWER BLOOD PRESSURE

CASE 9-1, QUESTION 12: Which lifestyle modifications can D.C. implement to lower his BP?

Weight reduction through dietary modifications and physical activity and sodium restriction are the most apparent lifestyle modifications for D.C. to lower his BP. A thorough patient interview (diet history to quantify total calories, sodium, fat, and cholesterol, and social history to determine alcohol consumption and confirm cigarette use) should be obtained. Based on this interview, customized recommendations can be made.

The DASH diet should be strongly encouraged in D.C. based on proven benefits.[23]

D.C.'s BMI of 30 kg/m^2 classifies him as obese. As little as a 5% to 10% loss in weight 11.02 to 24.25 pounds (5–11 kg) will provide global health benefits. Strategies that increase his aerobic activity, in addition to diet, can augment weight loss.

OTHER CARDIOVASCULAR RISK REDUCTION STRATEGIES

Smoking cessation

CASE 9-1, QUESTION 13: Aside from treating hypertension, which other CV risk reduction strategies should be recommended in D.C.?

Smoking is an important modifiable major CV risk factor. Cigarette smoking has been shown to independently increase CV and overall mortality, and cessation can decrease the incidence of CV disease.[45] Although smoking does not chronically lower BP, smoking cessation is strongly recommended to improve overall health. Hypertensive smokers should be continually educated about the risks associated with cigarette smoking and directed to behavior-modification programs that can assist smoking cessation efforts (see Chapter 91, Tobacco Use and Dependence).

Low-dose aspirin

The United States Preventive Services Taskforce (USPSTF) recommends initiating low-dose aspirin (81 mg daily) use for the primary prevention of CV disease and in adults ages 50 to 59 years who have a ≥10% 10-year ASCVD risk, are not at increased risk for bleeding, have a life expectancy of ≥10 years, and are willing to take low-dose aspirin daily for ≥10 years.[46] D.C. is not yet a candidate for low-dose aspirin based on his age.

Controlling other comorbid diseases

In addition to treating hypertension and lowering BP to goal, controlling other comorbidities, which are themselves associated with increased CV risk, should be performed. When present, dyslipidemia, diabetes mellitus, obesity, and any other forms of CV disease should be diligently treated and controlled. D.C. has dyslipidemia and requires statin treatment (individuals without clinical ASCVD or diabetes, who are age 40–75 years with LDL-C 70–189 mg/dL, and have an estimated 10-year ASCVD risk of ≥7.5%—D.C.'s calculated risk is 9.6%), and his CV risk would be reduced with better control of this condition (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).

Pharmacotherapy for Primary Prevention Patients

EVIDENCE-BASED RECOMMENDATIONS

Case 9-1, Question 14: Which treatment principles need to be considered when choosing an initial antihypertensive agent for D.C.?

Selecting an antihypertensive drug is complex. There are numerous choices, and all agents can effectively lower BP. Depending on the dose used, BP reductions are similar.[47] BP reduction, however, is only a surrogate end point of therapy and

does not necessarily reflect overall effectiveness. Reducing hypertension-associated complications is the ultimate goal of treatment.

Case 9-1, Question 15: Which antihypertensive agents are appropriate first-line treatments for D.C.?

Because D.C. is Black and does not have CKD, the 2017 ACC/AHA Hypertension Guidelines recommend thiazide-like diuretics or CCBs as first-choice antihypertensive therapy. This recommendation is based on the propensity of data showing reduced morbidity and mortality with these drug classes.[48]

Traditional landmark placebo-controlled hypertension studies (eg, the SHEP,[41] Swedish Trial in Old Patients with Hypertension,[33] and the Medical Research Council[31]) established that treating hypertension produces significant reductions in CV events (eg, stroke and MI) and mortality. These traditional landmark trials used thiazide diuretic–based therapy, and thus thiazide diuretics have been the quintessential antihypertensive agent for most patients. Subsequently, several clinical trials evaluating newer agents (ACEI, ARB, and CCB) have provided additional evidence on CV event reduction.[14,20,42,49–68] Most of these trials do not include a placebo group (because it is unethical to use placebo in long-term studies); rather, they use an active antihypertensive agent as the comparator (often a thiazide diuretic or β-blocker or both). In those studies in which newer antihypertensive agents were compared with thiazide diuretics, very similar effects were seen. One of these studies was the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).[50] In the ALLHAT, 33,357 patients with hypertension were randomly assigned in a double-blind manner to thiazide diuretic (chlorthalidone), CCB (amlodipine), or ACEI (lisinopril)-based therapy. After a mean follow-up to 4.9 years, the incidence of the primary end point of fatal CHD or nonfatal MI was similar among all three treatment arms.

Case 9-1, Question 16: Should monotherapy or two-drug therapy be started in D.C. as his initial regimen?

A monotherapy approach is an option for D.C. Monotherapy with a CCB, or thiazide diuretic as recommended, will likely reduce his BP to <130/80 mm Hg. If D.C. were not Black, an ACEI and an ARB would also be optimal alternatives.

SPECIAL POPULATIONS

Black patients

Case 9-1, Question 17: How should D.C.'s race influence the selection of an antihypertensive regimen?

As monotherapy, it is well documented that a thiazide diuretic or a CCB is highly effective in lowering BP in Black patients. This is likely because of the profile of low renin coupled with high plasma volume pattern of hypertension that is commonly seen in Black patients with hypertension. Conversely, ACEI, ARB, or β-blocker monotherapy is less effective in lowering BP in Black compared with White patients. However, when these agents are used in combination, especially with a thiazide diuretic, these race-based differences seen in BP lowering with monotherapy are abolished. This information may aid in selecting one drug option over another in a primary prevention patient, but does not apply to Black patients with other comorbidities, in whom choice of therapy follows an evidence-based approach to selection based on the comorbidities.

D.C. does not have any other comorbidities for specific antihypertensive drug therapy. His first-line treatment option is CCB or thiazide diuretic. Monotherapy with either a thiazide diuretic or a CCB would be very effective in BP lowering; either of these two drugs is an acceptable treatment option for him.

Elderly patients

CASE 9-2

QUESTION 1: B.D. is an 83-year-old female with a medical history of hypertension, osteoporosis, and hypothyroidism. Her present medications are levothyroxine 100 µg daily, alendronate 70 mg weekly, vitamin D 800 IU daily, and calcium carbonate 600 mg twice daily. She has been diagnosed with hypertension for 2 years, and it has been treated with lifestyle modifications (sodium restriction and exercise three times weekly). B.D. is 64 inches (162.56 cm) tall and weighs 121.25 pounds (55 kg). Her current BP is 160/78 mm Hg (160/80 mm Hg when repeated). All serum laboratory tests are normal. Her provider has been reluctant to start antihypertensive drug therapy because of B.D.'s age.

How is treatment of B.D.'s hypertension different from that of a younger patient?

Older patients with hypertension (age older than 65 years) have the lowest rates of BP control, and this rate decreases in even older populations.[1] Very elderly patients such as B.D., similar to Black patients, respond best to thiazides and CCBs and less to ACEIs, ARBs, and β-blockers when these are used as monotherapy. However, it is unclear whether these small differences in BP lowering among classes are clinically significant; thus, they are all recommended as first choice per treatment guidelines.

Isolated Systolic Hypertension

B.D. has isolated systolic hypertension (ISH), which is defined as an elevated SBP with a normal DBP.[2] This pattern of hypertension is most common in older patients and incurs a significant risk of CV disease. It was once thought that patients with ISH required high SBP to ensure normal perfusion of the heart and brain and that treating ISH would further lower DBP and worsen organ perfusion. Evidence clearly demonstrates, however, that treating ISH with antihypertensive drug therapy reduces the risk of CV events.[33,41,56] B.D.'s hypertension should be managed with drug therapy in addition to lifestyle modifications.

CASE 9-2, QUESTION 2: What data support antihypertensive drug therapy in patients who are very elderly, similar to B.D.?

The care of patients with ISH, including the very elderly, should follow the same general hypertension care principles that apply to all patients, except using a gentler dose initiation approach to reduce the risk of orthostatic hypotension. The 2017 ACC/AHA Guidelines support the same BP goal in the elderly with ASCVD risk ≥10% compared to younger patients (<130/80 mm Hg).[3] In SPRINT, prespecified subgroup analysis of the elderly cohort including those considered frail did sustain benefit from the lower BP target.[22] However, it recognized that lower doses should be used when first starting therapy in elderly patients because of the higher risk of developing orthostatic hypotension. Orthostatic hypotension occurs when standing upright results in an SBP decrease of >20 mm Hg (or a DBP decrease of >10 mm Hg) after 3 minutes of standing and is often accompanied by dizziness or fainting. This is a risk of rapid BP lowering. Orthostatic hypotension is more frequent in elderly patients (especially those with ISH), diabetes, autonomic dysfunction, volume depletion, and in patients taking certain drugs (ie, diuretics, nitrates, α-blockers, psychotropic agents, and phosphodiesterase inhibitors). Antihypertensive dose increases should be gradual to minimize the risk of hypotension. Moreover, initial therapy with two drugs should probably be avoided in the elderly (age 80 years or older) owing to the increased risk of orthostatic hypotension.

The very elderly (ie, patients 80 years or older) have traditionally been underrepresented in landmark placebo-controlled clinical trials. However, the HYVET was a placebo-controlled, randomized trial evaluating the effect of antihypertensive pharmacotherapy (ACEI with or without a thiazide-like diuretic) in patients with hypertension age 80 years or older.[22] This trial was stopped prematurely, after 1.8 median years, owing to a significant reduction in overall mortality in the treatment arm. The HYVET provides compelling evidence that treatment of hypertension in the very elderly provides significant benefits. B.D. should be started on a low-dose thiazide diuretic or CCB for the treatment of her hypertension. For elderly patients with existing incontinence, diuretic therapy will be problematic. Under this

circumstance, a CCB would be a more reasonable first-line option. Considering her advanced age, starting with monotherapy is appropriate to reduce her risk of orthostatic hypotension.

ADDITIONAL CONSIDERATIONS

CASE 9-3

QUESTION 1: You are developing a collaborative drug therapy management (CDTM) protocol for treatment of hypertension that will be used by clinical pharmacists. In your CDTM protocol, you include multiple pharmacotherapy options (ACEIs, ARBs, CCBs, and thiazide diuretics) as equally recommended in primary prevention patients. However, you wish to include additional guidance on how to select an individual drug class to treat hypertension.

What additional factors should be considered in your protocol when selecting a first-line agent for a specific primary prevention patient?

It cannot be emphasized enough that selecting pharmacotherapy should follow an evidence-based philosophy. In patients with other comorbidities, certain antihypertensive drug classes are recommended in place of other options. In patients without other comorbidities, factors such as concomitant diseases, medication costs, serum electrolytes, and prior medication intolerances should be considered (**Table 9-7**). These are helpful when selecting initial therapy for a patient requiring primary prevention and has more than one acceptable drug class as a first-line option or when selecting add-on therapy to further lower BP. These are discussed later in this chapter.

Table 9-7
Additional Considerations in Antihypertensive Drug Choice[a]

Antihypertensive Agent	Situations With Potentially Favorable Effects	Situations With Potentially Unfavorable Effects[b]	Avoid Use
ACEI	Low-normal potassium, elevated fasting glucose, microalbuminuria (with or without diabetes)	High-normal potassium or hyperkalemia	Pregnancy, bilateral renal artery stenosis, history of angioedema
ARB	Low-normal potassium, elevated fasting glucose, microalbuminuria (with or without diabetes)	High-normal potassium or hyperkalemia	Pregnancy, bilateral renal artery stenosis
CCB: dihydropyridine	Raynaud phenomenon, elderly patients with isolated systolic hypertension, cyclosporine-induced hypertension	Peripheral edema, left ventricular dysfunction (all except amlodipine and felodipine), high-normal heart rate or tachycardia	
CCB: nondihydropyridine	Raynaud phenomenon, migraine headache, supraventricular arrhythmias, high-normal heart rate or tachycardia	Peripheral edema, low-normal heart rate	Second- or third-degree heart block, left ventricular dysfunction
Thiazide diuretic	Osteoporosis or at increased risk for osteoporosis, high-normal potassium	Gout, hyponatremia, elevated fasting glucose (as monotherapy), low-normal potassium or sodium	

High-normal refers to patients in the high end of the normal range, but not above the range.

Low-normal refers to patients in the low end of the normal range, but not below the range.

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; CCB, calcium channel blocker.

[a]These considerations should never replace drug recommendations for a compelling indication.

[b]May use but requires diligent monitoring.

The costs of treating hypertension and related complications are substantial to patients and health systems.[69] With expanding availability of generic agents, costs attributed to drug acquisition are small in comparison with expenses for laboratory evaluations, office visits, and medical care for hypertension-associated complications. Whenever possible, affordable regimens that do not compromise efficacy should be designed. Generic antihypertensive products are equally effective and less expensive than are brand-name products, and all first- and second-line antihypertensive classes have generic alternatives. The frequency of administration can influence treatment. Once-daily administration assists adherence; all major drug classes contain agents that are either naturally long-acting or formulated in long-acting preparations.

Pharmacotherapy for Patients With Other Comorbidities

Case 9-3, Question 2: In your CDTM protocol, when should an ACEI or ARB be identified as first-line therapy ahead of other antihypertensive agents?

There are other coexisting diseases or hypertension-associated complications in patients that may warrant the use of certain classes of antihypertensive because these agents show significant benefits in reducing CV morbidity or mortality in patients with those specific comorbidities.

DIABETES

Kidney disease and CV disease are both long-term hypertension-associated complications that are at high risk for occurring in patients with diabetes. The 2017 ACC/AHA Hypertension Management Guidelines recommend the same four classes of antihypertensive agents as first choice in non-Black patients with diabetes for primary prevention of CV events (ACEI, ARB, CCB, and thiazide diuretics) and thiazide diuretics and CCB in Black patients.[3] When compared head to head, ACEIs are superior to dihydropyridine CCBs in reducing CV events.[59,60] Subgroup analyses of larger clinical trials further support CV event reduction with ACEIs and ARBs. Therefore, ACEI and ARB may be the preferred initial antihypertensive therapy for a patient with diabetes if there is no other contraindication.

Case 9-3, Question 3: In your CDTM protocol, how should significant CKD be defined so that patients with CKD can be identified and treated appropriately?

CHRONIC KIDNEY DISEASE

It is common that CKD presents initially with microalbuminuria (30–299 mg albumin in a 24-hour urine collection) that can progress over the course of several years to overt kidney failure.[32] Progression is

accelerated in the presence of both hypertension and diabetes. The 2017 ACC/AHA Hypertension Treatment Guidelines recommend ACEI (if intolerance is due to cough, ARB therapy) to be used as first-line therapy in patients with CKD if albuminuria (≥300 mg/day or ≥300 mg/g creatinine by first morning void) is present.[3] Both ACEI and ARB have also been shown to reduce the progression of CKD in type 1 diabetes,[68] in type 2 diabetes,[61,62] and in those without diabetes.[66-71] Recently, ARB therapy has also been shown to decrease risk of developing microalbuminuria in patients with diabetes.[72]

Although many of the long-term benefits of ACEI or ARB therapy may be from BP lowering, their evidence base is robust enough to support their first-line use in CKD.[73,74] After ACEI or ARB therapy has been implemented, data support a CCB as the second drug because this has been shown to reduce progression of CKD better than does a thiazide diuretic as the second drug added based on the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial.[73]

Patients with stage 3 to 4 CKD (eGFR of 20 to <60 mL/min/1.73 m^2) comprised 28% of the SPRINT study population, and, in this group, intensive BP management seemed to provide the same benefits for reduction in the CV disease composite primary outcome and all-cause mortality as were seen in the full study cohort. Given that most patients with CKD die from CV complications, based on evidence from SPRINT, the 2017 guidelines support patients with CKD with ASCVD risk >10% to have a lower BP target of <130/80 mm Hg.[22]

CHRONIC AND ACUTE CORONARY ARTERY DISEASE

CASE 9-3, QUESTION 4: In your CDTM protocol, although β-blocker is no longer considered as a first choice for primary prevention, are there any cases when β-blocker therapy would be identified as an appropriate first-line antihypertensive drug therapy?

The ACC and AHA have guidelines for chronic CAD that recommend treatment with a β-blocker, followed shortly thereafter by the addition of an ACEI.[75] β-Blockers (those without intrinsic sympathomimetic activity [ISA]) decrease the risk of a subsequent MI or sudden cardiac death by decreasing the adrenergic burden on the heart, and progression of coronary atherosclerosis. ACEI therapy promotes cardiac remodeling, improves cardiac function, and reduces the risk of CV events. An ARB is an alternative in patients who do not tolerate an ACEI, because fewer data that assess the long-term impact of an ARB on CV events compared with an ACEI in chronic CAD exist.[76,77] A thiazide diuretic can be added to the core regimen of a β-blocker with an ACEI (or ARB) if additional BP reduction is needed. However, if an additional agent is needed to treat ischemic symptoms for patients with chronic stable angina, a dihydropyridine CCB can be added to this core regimen. If a β-blocker cannot be used because of intolerance or contraindication, a nondihydropyridine CCB can be used as an alternative to a β-blocker. Acute CAD, also called acute coronary syndrome, includes unstable angina, non–ST-segment elevation MI, and ST-segment elevation MI. The ACC/AHA Guidelines for these conditions indicate a β-blocker as first-line pharmacotherapy.[78] The 2017 ACC/AHA Hypertension Treatment Guideline recommends that these patients have a BP goal of <130/80 mm Hg.[3]

LEFT VENTRICULAR DYSFUNCTION

Pharmacotherapy for left ventricular dysfunction should include a three-drug combination of an ACEI, a β-blocker, and an aldosterone antagonist, plus loop diuretics depending on the need for diuresis.[79] ACEIs, β-blockers, and aldosterone antagonists, all have numerous landmark clinical trials showing reduced morbidity and mortality rates, whereas diuretics provide primarily symptomatic relief of edema.[79]

According to evidence-based medicine principles, only metoprolol, carvedilol, and bisoprolol are indicated for left ventricular dysfunction. Other β-blockers (eg, atenolol) should not be used in

patients with left ventricular dysfunction because they do not have supporting data demonstrating that they reduce CV event rates in these patients. Patients should be clinically euvolemic and hemodynamically stable before adding a β-blocker. As discussed in Chapter 14, Heart Failure, it is important to start with very low doses of a β-blocker, then slowly titrate upward over the course of several weeks to the recommended dosing range for left ventricular dysfunction. An ARB can be used as an alternative to an ACEI.[79]

Potassium serum concentrations must be carefully monitored in the situation when an ACEI (or ARB) and an aldosterone antagonist are used together. Alternatively, the combination of hydralazine with isosorbide dinitrate can be added in Black patients.[80] This combination has been demonstrated to improve CV outcome in this patient population. The 2017 ACC/AHA Hypertension Treatment Guideline recommends that these patients have a BP goal of <130/80 mm Hg.[3]

Monitoring Therapy

Four aspects of treatment must always be considered: (a) BP response to attain goal, (b) adherence to lifestyle modifications and pharmacotherapy, (c) progression to hypertension-associated complications, and (d) drug-related toxicity.

Reduction in BP should be evaluated 1 to 4 weeks after starting or modifying therapy for most patients. BP usually begins to decrease within 1 to 2 weeks of starting an agent, but steady-state antihypertensive effects can take up to 4 weeks. If patients are in hypertensive crisis, evaluation should occur sooner, within hours to days (see Chapter 16, Hypertensive Crises).

Two BP values separated by at least 1 minute should be measured during each clinical evaluation, with the average used to make a proper assessment. If dehydration or orthostatic hypotension is suspected, BP should be measured in both the seated and standing positions to detect orthostatic changes. For routine monitoring, measuring BP in the seated position is sufficient. Self-BP

monitoring values should be considered if available. Normally, however, they are slightly lower (5 mm Hg) than are clinical values even in patients without white-coat hypertension. For example, patients with a goal BP value of <140/90 mm Hg should have home measurements that are <135/85 mm Hg.[9]

All patients should be questioned in a nonthreatening manner regarding adherence to lifestyle modifications and drug therapy. This is especially important for complex regimens, when drug intolerance is likely, or when financial constraints hinder acquisition of medications. Evaluating hypertension-associated complications and drug side effects are essential. New hypertension-associated complications may necessitate changes to treat a compelling indication or attain a new BP goal. Drug-related side effects may similarly require therapy modifications.

CASE 9-4

QUESTION 1: B.A. is a 58-year-old White female who is postmenopausal, does not smoke, and never drinks alcohol. Since being diagnosed with hypertension, she has modified her diet, begun routine aerobic exercise, and has lost 22.04 pounds (10 kg) in the past 18 months. She now weighs 158.73 pounds (72 kg) and is 64.96 inches (165 cm) tall. Her BP is now 150/94 mm Hg (150/92 mm Hg when repeated) and has consistently remained near this value for the past year. Her BP when first diagnosed was 156/96 mm Hg. Physical examination shows no LVH and no retinopathy. Urinalysis is negative for protein. Other laboratory tests are normal, except for dyslipidemia (total cholesterol 200 mg/dL, HDL 38 mg/dL, LDL120 mg/dL). B.A. has no health insurance and is concerned about the cost of therapy. She takes over-the-counter calcium with vitamin D, and her provider wants to start HCTZ 25 mg/day.

Is HCTZ an appropriate agent for B.A.?

CLINICAL SCENARIOS

Diuretics

B.A. is a primary prevention patient with uncontrolled hypertension. Her 10 years' calculated ASCVD risk is 4.7%. According to 2017 ACC/AHA Guidelines, her BP goal is <140/90 mm Hg.[2,3] Initial monotherapy is reasonable. Appropriate first-line treatment options include an ACEI, ARB, a CCB, or thiazide diuretic. All these drug classes have generic options and should be easily affordable for B.A. A thiazide diuretic may also benefit her osteoporosis (Table 9-7) and is an appropriate choice. Several types of diuretics are used to manage hypertension (**Table 9-8**).[30] All lower BP, with differences being duration of action, potency of diuresis, and electrolyte abnormalities.

Table 9-8
Diuretics in Hypertension

Category	Selected Products	Usual Dosage Range (mg/day)	Dosing Frequency
Thiazide and thiazide-like	Chlorthalidone	12.5–25	Daily
	Hydrochlorothiazide	12.5–25	Daily
	Indapamide	1.25–5	Daily
	Metolazone	2.5–10	Daily
	Metolazone	0.5–1.0	Daily
Loop	Bumetanide	0.5–4	bid
	Furosemide	20–80	bid
	Torsemide	2.5–10	Daily
Potassium sparing	Amiloride	5–10	Daily to bid
	Triamterene	50–100	Daily to bid
Potassium-sparing combination	Triamterene/HCTZ	37.5/25–75/50	Daily
	Spironolactone/HCTZ	25/25–50/50	Daily
	Amiloride/HCTZ	5–10/50–100	Daily
Aldosterone antagonist	Eplerenone	50–100	Daily to bid
	Spironolactone	12.5–50	Daily to bid

bid, two times daily; HCTZ, hydrochlorothiazide.

THIAZIDES

Thiazides are diuretics of choice for most patients with hypertension. Similar to loop diuretics, an initial diuresis is experienced. After approximately 4 to 6 weeks of thiazide diuretic therapy, the diuresis dissipates. In exchange, it has a consistent PVR reduction effect, which is responsible for sustaining antihypertensive effects.

Case 9-4, Question 2: How should a thiazide diuretic be started in B.A.?

Hydrochlorothiazide versus chlorthalidone

HCTZ and chlorthalidone have been used in several major outcome trials, although only chlorthalidone-based regimens have proved to be of benefit in the low doses commonly used in practice today.[31,33,41,50,56,81,82] Both agents are inexpensive and dosed once daily, but HCTZ is most frequently used in the United States and is more widely available in fixed-dose combination products. The usual starting dose of HCTZ or chlorthalidone is 12.5 mg once daily. A maintenance dose of 25 mg once daily can effectively lower BP and has a low incidence of side effects (eg, hypokalemia and hyperuricemia) that can be managed with routine monitoring.[35,47,48]

Significant controversy surrounds the comparative efficacy of HCTZ and chlorthalidone. Most clinicians assume a class effect for these two drugs.[10] However, class effects can be legitimized only after assurance of equipotent dosing; for antihypertensives, when they are not directly compared in a CV event trial, it assumes that if two agents achieve similar BP lowering, then both achieve similar reduction in CV events. With regard to HCTZ and chlorthalidone, this assumption is unproven. Chlorthalidone is more potent on a milligram-per-milligram basis and has a longer half-life than does HCTZ (50–60 vs 9–10 hours).[83] Based on a comparative study using 24-hour ABPM, it appears that the equipotent dose of chlorthalidone 25 mg daily is HCTZ 50 mg daily, but this dose of HCTZ is unpopular because of increased side effects. Consequently, it is believed by some that the antihypertensive efficacy of chlorthalidone is greater than that of HCTZ when contemporary doses are used; the 12.5- to 25-mg doses of chlorthalidone do not appear to significantly increase the risk of hypokalemia more so than does HCTZ.[84] Complicating this issue is evidence demonstrating that office BP tends to overestimate the response to HCTZ, and the 24-hour BP lowering with HCTZ is only comparable to other common agents (ACEI, ARB, CCB, and even β-blockers) when 50 mg daily is used.[85] Data from

the Multiple Risk Factor Intervention Trial indicate that chlorthalidone reduces CV events more than does HCTZ.[85] Although chlorthalidone is the most optimal and evidence-based thiazide diuretic for B.A., HCTZ remains currently accepted in the clinical environment as a reasonable thiazide diuretic for hypertension assuming her BP goal can be readily achieved with its use.

LOOP DIURETICS

Loop diuretics produce a more potent diuresis, but a smaller decrease in PVR, and less vasodilation than do thiazide diuretics. They are subject to a significant postdose antinatriuretic period, which offsets their antihypertensive effect. Therefore, a thiazide is more effective at lowering BP than are loop diuretics in most patients. Loop diuretics are usually considered only for patients with severe CKD (eGFR <30 mL/min/1.73 m^2), left ventricular dysfunction, or severe edema. In these patients, potent diuresis is often needed. Furosemide has a short duration of effect and should be given twice daily when used in hypertension, whereas torsemide has a longer duration of action and can be given once daily.

POTASSIUM-SPARING DIURETICS

Potassium-sparing diuretics (triamterene and amiloride) should be reserved for patients who experience hypokalemia while on a thiazide diuretic. With low-dose thiazide diuretics, <25% of patients develop hypokalemia, and most cases are not severe. Triamterene and amiloride usually do not provide significant additional BP lowering when added to a thiazide diuretic. Several fixed-dose products that include HCTZ with triamterene or amiloride are available. Empirically starting all patients with hypertension treated with a thiazide diuretic on triamterene or amiloride to avoid hypokalemia is not rational or necessary unless baseline serum potassium is in the low-normal range.

A thiazide diuretic is an optimal first-line option in primary prevention in patients such as B.A., and she has no contraindications (**Table 9-9**). Although B.A. has dyslipidemia,

thiazide diuretics are unlikely to have a clinically significant effect on cholesterol when used in low doses.[86,87] An appropriate starting dose of HCTZ is 12.5 or 25 mg daily. B.A. has no additional risks for orthostatic hypotension, so starting at the higher 25-mg daily dose is safe and will have a better chance of lowering her BP to goal than the lower 12.5-mg dose because most antihypertensive agents provide a 10-mm Hg reduction in SBP and 5-mm Hg reduction in DBP with a standard starting dose.[88]

Table 9-9
Side Effects and Contraindications of Antihypertensive Agents

	Side Effects			Contraindications
	Innocuous but Sometimes Annoying	**Potentially Harmful**	**Usually Requires Cessation of Therapy, at Least Temporarily**	
Thiazide diuretics	Increased urination (at onset of therapy), muscle cramps, hyperuricemia (without gout)	Hypokalemia,[a] hyponatremia, hyperglycemia, hypovolemia, pancreatitis, photosensitivity, hypercholesterolemia, hypertriglyceridemia, hyperuricemia with gout, orthostatic hypotension (more frequent in elderly)	Hypercalcemia, azotemia, skin rash (cross-reacts with only certain sulfonamide allergies), purpura, bone marrow depression, lithium toxicity in patients on lithium therapy, hyponatremia	Anuria, kidney failure
Loop diuretics	Increased urination, muscle cramps, hyperuricemia (less than with thiazides)	Hypokalemia,[a] hyperglycemia, hypovolemia, pancreatitis, hypercholesterolemia, hypertriglyceridemia, hearing loss with large IV doses, orthostatic hypotension (more pronounced in the elderly)	Hyponatremia, hypocalcemia, azotemia, skin rash (cross-reacts with only certain sulfonamide allergies), photosensitivity, lithium toxicity in patients on lithium therapy	Anuria
ACEI	Dizziness, dry cough	Orthostatic hypotension (more pronounced in the elderly treated with a diuretic), increased serum creatinine, increased potassium	Angioedema, severe hyperkalemia, increase in serum creatinine >35%	Bilateral renal artery stenosis, volume depletion, hyponatremia, pregnancy, history of angioedema
ARB	Dizziness	Orthostatic hypotension (more pronounced in the elderly treated with a diuretic), increased serum creatinine, increased potassium	Severe hyperkalemia, increase in serum creatinine >35%	Bilateral renal artery stenosis, volume depletion, hyponatremia, pregnancy
CCB: dihydropyridines	Dizziness, headache, flushing	Peripheral edema, tachycardia	Significant peripheral edema	Left ventricular dysfunction (not with amlodipine or felodipine)
CCB: nondihydropyridines	Dizziness, headache, constipation	Bradycardia	Heart block, left ventricular dysfunction, interactions with certain drugs	Left ventricular dysfunction, second- or third-degree heart block, sick sinus syndrome
β-Blocker	Bradycardia, weakness, exercise intolerance	Masking the symptoms of hypoglycemia in diabetes, hyperglycemia, aggravation of peripheral arterial disease, erectile dysfunction, increased triglycerides, decreased HDL-C	Left ventricular dysfunction (not with carvedilol, metoprolol, bisoprolol), bronchospasm in patients with asthma or COPD (more pronounced with nonselective agents)	Severe asthma, second- or third-degree heart block, acute left ventricular dysfunction exacerbation, coronary artery disease for agents with intrinsic sympathomimetic activity
Aldosterone antagonist	Menstrual irregularities (spironolactone only) or gynecomastia (spironolactone only)	Increased potassium	Hyperkalemia, hyponatremia	Kidney failure. kidney impairment (for eplerenone: CrCl <50 mL/min, or type 2 diabetes with proteinuria, and creatinine >1.8 in females, >2.0 in males), hyperkalemia, hyponatremia

ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; CCB, calcium channel blocker; COPD, chronic obstructive pulmonary disease; CrCl, creatinine clearance; HDL-C, high-density lipoprotein cholesterol; IV, intravenous.

[a]Routine addition of potassium supplementation or empiric concurrent potassium-sparing diuretics should be discouraged unless hypokalemia is demonstrated, the patient is taking digoxin, or potassium is in the low-normal range.

PATIENT EDUCATION

CASE 9-4, QUESTION 3: B.A. is prescribed HCTZ 25 mg daily. How should she be counseled regarding this therapy?

Several counseling points are summarized in Table 9-6. Some patients disregard lifestyle modifications when they start antihypertensive therapy, so B.A. must be encouraged to continue lifestyle modification to maximize her response to drug therapy. B.A. should be informed that diuretics lower both BP and risk of CV events, and that taking her dose at about the same time each morning to minimize nocturia and provide consistent effects is recommended. B.A. should expect to experience increased urination when starting HCTZ, but she should be informed that this diminishes with time. Inform B.A. that missed doses should be taken as soon as possible within the same day, but doubling doses the next day is not recommended. The potential for hypokalemia, which is easily identified and managed, and the need for routine monitoring of serum potassium should be reviewed. She should be counseled on the signs and symptoms of electrolyte abnormalities (eg, leg cramps and muscle weakness) and encouraged to report these to her health care provider if they occur. Increasing dietary intake of potassium-rich foods to minimize electrolyte depletion is an option to minimize potassium loss. This should be encouraged only with thiazide and loop diuretics, but not with potassium-sparing agents.

Despite improvements with lifestyle modifications and reported adherence to HCTZ, B.A.'s goal BP of <140/90 mm Hg has not been met (her BP average is 141/83 mm Hg). No new signs of hypertension-associated complications are seen. She should be encouraged to continue with her current efforts, but other interventions are warranted.

CASE 9-4, QUESTION 4: After 4 weeks of HCTZ 25 mg daily, B.A. has no problems and has not missed a dose. She is exercising and is following the DASH diet. Her BP values are 142/86 mm Hg (140/84 mm Hg when repeated). Her fasting laboratory values are as follows:

Serum potassium, 3.8 mEq/L
Uric acid, 7.3 mg/dL
Glucose, 99 mg/dL

All other values are unchanged. Last month, potassium was 4.0 mEq/L, uric acid was 6.8 mg/dL, and fasting glucose was 95 mg/dL. What is your assessment regarding the efficacy and toxicity of B.A.'s antihypertensive therapy?

POTASSIUM LOSS

Adverse reactions with low-dose thiazide diuretics (eg, HCTZ 12.5–25 mg daily) are minimal compared with higher dose therapy (HCTZ >25 mg daily). Moreover, side effects and tolerability with low-dose thiazide diuretic therapy are similar to other first-line drug therapy options and not much higher than what is seen with placebo.[35,37,38] Regardless, signs and symptoms of electrolyte and metabolic changes, such as hypokalemia, hyponatremia, hyperglycemia, or hyperuricemia, should be evaluated in all patients treated with thiazide diuretics. B.A. has experienced small changes in serum potassium and uric acid, which are typical thiazide-induced abnormalities. B.A. should be questioned about muscle cramps or weakness, which can be caused by decreased potassium.

CASE 9-4, QUESTION 5: Is B.A.'s potassium decrease concerning? If so, how should this be managed?

Most total body potassium is intracellular (~98%). Thiazide diuretics can cause potassium loss and can result in potassium serum concentrations in the low end of the normal range. However, with low-dose therapy, overt hypokalemia is not common. HCTZ in doses of 12.5, 25, and 50 mg daily can decrease serum potassium by an average of 0.21, 0.34, and 0.5 mEq/L, respectively.[35,87,89] This is usually considered mild, with serum potassium concentrations reaching a nadir within the first month of therapy and remaining stable thereafter. Restriction of dietary sodium in patients receiving diuretic therapy has been shown to reduce the loss of potassium and should be encouraged in B.A.[90]

Hypokalemia

Case 9-4, Question 6: When is potassium correction needed to manage diuretic-induced hypokalemia?

B.A.'s potassium is within the normal range. Potassium replacement is not indicated. Diuretic-associated hypokalemia should be treated when serum concentrations are below normal regardless of whether symptoms (eg, muscle cramps) are present. Serum potassium should be measured at baseline and 2 to 4 weeks after initiating therapy or increasing the diuretic dose.

Potassium-rich foods (eg, dried fruit, bananas, potatoes, and avocados) may help prevent small decreases in potassium, but they cannot be used as sole therapy to correct hypokalemia. For instance, one medium-size banana has only 11.5 mEq of potassium. The usual replacement dose of prescribed potassium chloride is 20 to 40 mEq/day but can range from 10 to >100 mEq/day. Potassium chloride, bicarbonate, gluconate, acetate, and citrate salts are available for potassium replacement therapy. Rather than supplement potassium, which does not effectively correct the underlying mechanisms responsible for hypokalemia, a more appropriate and effective strategy to manage diuretic-induced hypokalemia is to add a potassium-sparing diuretic. Hypomagnesemia often accompanies diuretic-induced hypokalemia and must be normalized before hypokalemia can be effectively reversed.

Other metabolic abnormalities

Case 9-4, Question 7: How should the increase in B.A.'s uric acid be managed?

Thiazide diuretics can increase serum uric acid concentrations in a dose-dependent manner. Uric acid increases also occur with loop diuretics, but to a lesser extent. Increased proximal tubular renal

reabsorption, decreased tubular secretion, or increased postsecretory reabsorption of uric acid contributes to diuretic-induced hyperuricemia. Thiazide-induced hyperuricemia is usually small (≤0.5 mg/dL) and is not clinically significant in patients without a history of gout.[88] For patients with a history of gout, diuretics are not contraindicated, but an increase in serum uric acid may require a decrease in dose or possibly discontinuation of the diuretic, especially for those not on preventive antihyperuricemic therapy (eg, allopurinol and febuxostat). Acute gouty arthritis precipitated by diuretic therapy should be treated, and the diuretic should be dose reduced or discontinued, at least temporarily. Future use of the diuretic will depend on whether long-term antihyperuricemic therapy is to be added and the risk versus benefit for continuing the diuretic. B.A.'s serum uric acid concentration is elevated, but switching to a different agent or lowering the dose of HCTZ is unnecessary because she has no symptoms of gout.

It should be noted that changes in parameters such as uric acid can be informative regarding dosing. When a given dose of a diuretic fails to lower BP, it is often unclear as to whether the failure is a result of mechanisms other than volume driving the hypertension or a result of the diuretic dose being insufficient to achieve the desired physiologic effect. For example, the absence of an increase in uric acid suggests that the administered dose was insufficient, and that a higher dose merits consideration. In B.A.'s case, the increase in uric acid confirms that the given dose was sufficient to have had a physiologic effect, so adding an antihypertensive agent from a different drug class would be preferable to increasing the diuretic dose if further BP lowering is necessary.

Case 9-4, Question 8: How much will HCTZ alter B.A.'s cholesterol values?

Small increases in LDL-C and triglycerides are potential side effects of diuretic therapy. Dietary fat restrictions help minimize, but do not necessarily prevent, these effects. Contrary to other biochemical disturbances, diuretic-induced changes in the lipid

profile are not dose related, and overall changes are small. Many clinical trials lasting >1 year have shown that these alterations with diuretic therapy are not sustained with prolonged use.[86,87] Even if these changes are persistent, they are very small and are not clinically significant. The presence of dyslipidemia should never be a reason to avoid diuretic therapy.

Case 9-4, Question 9: What other potential electrolyte abnormalities should be evaluated in B.A. because of her thiazide diuretic therapy?

Hyponatremia is a serious, yet infrequent, adverse effect of diuretics. Changes in sodium concentrations are usually small, and most patients are usually asymptomatic. Frail, elderly females appear more susceptible to experiencing severe hyponatremia (<120 mEq/L) from diuretics, which rarely occurs, but requires discontinuation of therapy. Attention should be paid to the presence of other medications that can contribute to hyponatremia (eg, selective serotonin reuptake inhibitors and psychotropic drugs), and patients should be counseled to avoid excessive free water intake.

Hypomagnesemia is an often-overlooked metabolic complication of diuretic therapy. Both thiazide and loop diuretics increase urinary excretion of magnesium in a dose-dependent manner. Symptoms of significant hypomagnesemia include muscle weakness, muscle tremor or twitching, mental status changes, and cardiac arrhythmias. The presence of these symptoms would necessitate magnesium supplementation or use of a potassium-sparing agent as noted earlier if hypokalemia is also present.

Thiazide diuretics decrease urinary calcium excretion and can be used to prevent calcium-related kidney stones. The retention of calcium does not significantly increase serum calcium concentrations and does not place patients at risk for hypercalcemia. This effect, however, may be beneficial in females at risk for osteoporosis (eg, postmenopausal) such as B.A. or in patients with osteoporosis. Conversely, loop diuretics increase renal clearance of calcium.

Reasons for Inadequate BP Control

Case 9-4, Question 10: What are the common reasons for inadequate patient response to antihypertensive pharmacotherapy?

B.A. has been on her current dose of HCTZ for 4 weeks. The full antihypertensive effect of HCTZ should have been achieved, but she still has uncontrolled hypertension. She has had a response, but it remains inadequate. Potential reasons for an inadequate response, or lack of attaining BP goal values, with an antihypertensive should be considered before modifying her drug therapy regimen (**Table 9-10**). A comprehensive medication history and medical evaluation is needed to rule out identifiable causes, in particular nonadherence to the prescribed regimen. Her BP reduction with HCTZ is typical. Her kidney function is good, and no evidence exists of edema, so volume overload is unlikely. There are no apparent secondary causes of elevated BP. It is reasonable to conclude that B.A. needs additional therapy to achieve her goal BP. It is very common that most patients require two or more agents to attain BP goal values.

Table 9-10
Reasons for Not Attaining Goal Blood Pressure Despite Antihypertensive Pharmacotherapy

Drug Related	Health Condition or Lifestyle Related	Other
Nonadherence	Volume overload	Improper blood pressure measurement
Inadequate antihypertensive dose	Excess sodium intake	Resistant hypertension
Inappropriate antihypertensive combination therapy	Volume retention from chronic kidney disease	White-coat hypertension
Inadequate diuretic therapy	Secondary disease causes (Table 9-2)	Pseudohypertension

Secondary drug-induced causes (Table 9-2)	Obesity	
Clinician's failure to intensify or augment therapy (ie, clinical inertia)	Excessive alcohol intake	

Modifying Therapy

When a patient cannot achieve optimal BP control with initial antihypertensive, it is recommended that the dose of the first drug may be increased (if the patient has not yet achieved maximum dose of the agent), or a low dose of a second agent may be added. Second agents of choice would be ACEI, ARB, CCB, or thiazide diuretics, whichever one the patient is not already taking.[2] B.A.'s present dose of HCTZ is appropriate and should not be increased to the maximal recommended dose of 50 mg daily (considered high-dose therapy) because it may increase risk of electrolyte and metabolic side effects. B.A.'s potassium dropped to 3.8 mEq/L with HCTZ, and further dosage increases may produce hypokalemia (<3.5 mEq/L) requiring correction. Her hyperuricemia may also be worsened. The slightly increased antihypertensive response expected from increasing to 50 mg/day is therefore not justified.[85] Discontinuing HCTZ and starting a different agent is an option, but it is not prudent to abandon the HCTZ; she tolerated the treatment and experienced a reasonable BP response, and the HCTZ will augment the efficacy of nearly any other agent that may be added and may benefit her osteoporosis.

TWO-DRUG REGIMENS

The role of two-drug regimens in the treatment of hypertension is very clear. Most patients require multiple agents for BP control.

Adding a second agent to B.A.'s regimen is needed to reduce BP to her goal. She is a primary prevention patient, so three potential add-on antihypertensive agents that are considered first line include an ACEI, ARB, or a CCB. Ideally, a combination of two drugs with

different mechanisms of action should be selected to produce a complementary effect to lower BP.

Adding an ACEI or ARB to B.A.'s HCTZ will result in additive antihypertensive effects that are independent of reversing fluid retention. Diuretics reduce BP initially by decreasing fluid volume but maintain their antihypertensive effects by lowering PVR. BP lowering, however, can stimulate renin release from the kidney and activate the RAAS. This compensatory mechanism is an in vivo attempt to neutralize BP changes and regulate fluid loss. An ACEI or ARB blocks the RAAS, explaining why combinations of these agents with diuretics are additive. Data from the ACCOMPLISH trial support combination therapy for hypertension. In this randomized, double-blind trial, 11,506 patients with hypertension were randomly assigned to the combination of an ACEI with thiazide diuretic or an ACEI with a CCB.[91] After a mean follow-up of 3 years, the risk of CV events was significantly lower with the ACEI with CCB combination. Switching B.A.'s HCTZ to an ACEI with a CCB may be more effective in lowering CV events than adding an ACEI to her current HCTZ. This would be an acceptable modification. However, considering her response to HCTZ, simply adding an ACEI is also reasonable.

Fixed-dose combination products

Several fixed-dose combination products including two or three drugs are available.

Although individual dose titration is not simple with fixed-dose combination products, their use can reduce the number of tablets or capsules taken by patients. This has been demonstrated to improve adherence compared with using two separate single-drug products.[92] Improved adherence may increase the likelihood of achieving goal BP values.

Most fixed-dose combinations include a thiazide diuretic, and many are available generically. Other fixed-dose combination products combine a CCB with either an ACEI or ARB. These combinations, similar to a thiazide with an ACE or ARB, are highly

effective in lowering BP. An economic advantage may even exist to using a fixed-dose combination if it allows the patient to receive two drugs for one medication copayment. The Simplified Treatment Intervention to Control Hypertension Study demonstrated that initiating therapy with a fixed-dose combination product according to a treatment algorithm was superior in attaining goal BP values when compared with usual management according to national guidelines.[93] These data further support using a fixed-dose combination product for initial therapy.

B.A. is a candidate for a fixed-dose combination product. If the combination of an ACEI with HCTZ is selected for her, many options exist. All of the products with an ACEI also include HCTZ at the dose she is currently on. If the combination of an ACEI with a CCB is selected, fewer options exist, but there are products that contain an ACEI with a dihydropyridine CCB or a nondihydropyridine CCB. Cost should be considered because this is a concern for B.A. Multiple ACEI with thiazide diuretic combinations are available generically, but there is only one generic ACEI with CCB combination. Many ARBs are gradually becoming generic, so those may be potential options as well; therefore, a combination of ARB plus thiazide diuretic may also be an option eventually.

Angiotensin-Converting Enzyme Inhibitor

CASE 9-5

Question 1: A.R. is a 49-year-old Black female with type 2 diabetes. She started lisinopril 10 mg daily 2 weeks ago when her BP values were around 155/90 mm Hg. Since then, she has had weekly BP measurements, and her values have averaged 145/85 mm Hg despite strict adherence to her lifestyle modifications. Her BP today is 144/84 mm Hg (142/88 mm Hg when repeated), and her heart rate is 78 beats/min. She is not a smoker, and her BMI is 29 kg/m^2. All her laboratory test results, including kidney function, are within normal limits, except that her spot urine albumin-to-creatinine ratio is 80 mg/g (2 weeks ago it was 90 mg/g).

Is 2 weeks of lisinopril therapy long enough to assess her antihypertensive response?

Several ACEIs are available (**Table 9-11**). Most ACEIs are dosed once daily in hypertension (Table 9-11). In general, most ACEIs, if used in equivalent doses, are considered interchangeable.

Table 9-11
Angiotensin-Converting Enzyme Inhibitors in Hypertension

Drug	Usual Starting Dose (mg/day)[a]	Usual Dosage Range (mg/day)	Dosing Frequency
Benazepril	10	20–40	Daily to bid
Captopril	25	50–100	bid to tid
Enalapril	5	10–40	Daily to bid
Fosinopril	10	20–40	Daily
Lisinopril	10	20–40	Daily
Moexipril	7.5	7.5–30	Daily to bid
Perindopril	4	4–16	Daily
Quinapril	10	20–80	Daily to bid
Ramipril	2.5	2.5–20	Daily to bid
Trandolapril	1	2–4	Daily

bid, two times daily; tid, three times daily.

[a]Starting dose may be decreased 50% if patient is volume depleted, has acute heart failure exacerbation, or is very elderly (75 years or older).

The time to reach steady-state BP conditions is similar to what is seen with other antihypertensive agents. It may take several weeks before the full antihypertensive effects of ACEIs are seen. Therefore, evaluating BP response 2 to 4 weeks after starting or changing the dose of an ACEI is appropriate. A.R. has been taking lisinopril for 2 weeks, and her present BP should be used to determine whether she has attained goal BP. Both her BP range during the past few

weeks and today's average BP are above her goal of <140/90 mm Hg.

Case 9-5, Question 2: Why should A.R. have serum potassium and serum creatinine monitored while on lisinopril therapy?

Serum potassium can increase with ACEI therapy as a result of aldosterone reduction. Potassium increases with ACEI monotherapy are small (typically 0.1–0.2 mEq/L) and usually do not cause hyperkalemia. This risk is increased when ACEIs are used in patients with significant CKD (GFR <60 mL/min/1.73 m^2) or when they are used in combination with other drugs that can also raise potassium.

ACEI therapy can also cause a small increase in serum creatinine owing to decreased vasoconstriction of the efferent arteriole in the kidney. This results in a minor decrease in GFR that may be evidenced by a small increase in serum creatinine. A common mistake is to discontinue an ACEI in response to this rise in serum creatinine. Increases in serum creatinine of up to 30% from the baseline creatinine value are safe and anticipated. In these patients, the ACEI should be continued because a strong association exists between acute increases in serum creatinine of up to 30% that stabilize within the first 2 months of ACEI therapy and long-term preservation of renal function.[94] Patients with an increase in serum creatinine of >30% should have their ACEI therapy temporarily discontinued, because this may indicate other medical problems. Some of these problems can be underlying renal disease (such as bilateral renal artery stenosis) or other situations that may be compromising renal blood flow (eg, volume depletion, concomitant nonsteroidal anti-inflammatory drug therapy, and heart failure). Serum potassium and serum creatinine, in addition to BP, should be monitored in A.R. within 2 to 4 weeks of starting ACEI therapy or increasing the dose.

Case 9-5, Question 3: A.R.'s lisinopril dose is increased to 20 mg daily. Will this doubling of her dose place her at risk for significant hypotension?

The very elderly patients with volume depletion and patients with heart failure exacerbation may experience a significant first-dose response to an ACEI. This can manifest as orthostatic hypotension, dizziness, or syncope. The increased pretreatment activity of the RAAS, coupled with blockade of this system, explains this effect. In these patients, ACEI therapy should be initiated at half the normal dose (Table 9-11), followed by slow titration to standard doses.

Concurrent diuretic therapy may predispose some patients to first-dose hypotension. When ACEIs were first approved, dosing guidelines recommended starting at half the standard dose of the ACEI, decreasing the dose of the diuretic, or stopping the diuretic before initiating the ACEI. This was owing to fear that BP would sharply and acutely drop. These dosing recommendations are not necessary unless the patient is hemodynamically unstable (volume depleted, hyponatremic, or has poorly compensated heart failure) or very elderly. A.R. does not have any of these characteristics and can safely increase her dose of lisinopril.

Case 9-5, Question 4: Is an ACEI an effective therapy in a Black patient such as A.R.?

ACEI monotherapy is generally more effective at lowering BP in White patients than in Black or elderly patients. In fact, the 2017 ACC/AHA Hypertension Treatment Guideline does not recommend the use of ACEI or ARB as first-choice antihypertensive in Black patients for primary prevention, including those with diabetes (unless they have CKD or other comorbidities such as coronary artery disease or heart failure with reduced ejection fraction that may benefit from ACEI or ARB to improve CV outcomes).[2,3] Elderly and Black patients are more likely to have low renin hypertension, which may partially explain some of the differences in response. Nevertheless, many of these patients still respond to ACEIs as

monotherapy just to a less extent. Combination therapy, especially with a thiazide diuretic, usually mitigates this race- and age-related difference in BP response.

When an antihypertensive agent is being selected as initial monotherapy in a Black patient, an ACEI should generally not be chosen unless the patient has CKD. A thiazide diuretic or CCB is otherwise preferred. In this case, considering switching to a different agent (thiazide and CCB) may be a good alternative to improve A.R.'s BP control. Of note, Black patients have a two- to fourfold increased risk of angioedema and cough with ACEIs compared with White patients.[95] This does not preclude ACEI use in Black patients unless there is a prior history of angioedema.

Case 9-5, Question 5: A.R. has microalbuminuria, and lisinopril may help preserve kidney function. Is there a risk that lisinopril can cause acute renal dysfunction?

The ACEIs are effective in patients with hypertension-associated renal disease. They are contraindicated, however, in several situations, including bilateral renal artery stenosis, pregnancy, and volume depletion (Table 9-9). In the case of bilateral renal artery stenosis or volume depletion, high angiotensin concentrations maintain renal blood flow, and acute renal dysfunction can occur when an ACEI is started. Because it is often not known whether a patient has bilateral renal artery stenosis, problems with ACEI can be minimized by starting with recommended doses and careful monitoring of serum creatinine within 2 to 4 weeks of starting therapy. Modest elevations in serum creatinine that are <30% (for baseline creatinine values <3.0 mg/dL) do not warrant adjustment in therapy.[94] If greater increases occur, ACEI therapy should be stopped, and further medical evaluation should occur. Patients with elevated serum creatinine at baseline (up to 3.0 mg/dL) may particularly benefit from the vasodilatory effects of ACEIs in the kidney, but they require careful drug initiation and close monitoring. A.R.'s serum creatinine was normal after 4 weeks of lisinopril

therapy. She is not experiencing any kidney-related adverse effects from lisinopril.

Case 9-5, Question 6: What are the risks of using ACEIs in females of childbearing age?

Because ACEIs are teratogenic in the second and third trimester,[96] their use in pregnancy is contraindicated. Moreover, their use in females of childbearing potential is discouraged. If used in this population, patient education should be explicitly clear regarding risks to the fetus, which include potentially fatal hypotension, anuria, renal failure, and developmental deformities. A highly effective form of contraception should be strongly recommended.

Angiotensin-Receptor Blockers

Case 9-5, Question 7: A.R.'s lisinopril is increased to 20 mg daily, then to 40 mg daily during a period of 8 weeks. Her current BP is 136/78 mm Hg (134/76 mm Hg when repeated) at an office visit today. Her serum potassium and creatinine are unchanged from previous values. However, she reports a persistent dry cough for the past few months. She has no additional signs suggesting upper respiratory infection or left ventricular dysfunction. How should A.R.'s therapy be modified?

A well-known side effect of ACEIs is a nonproductive, dry cough, which can occur in up to 15% of patients, with some estimates of cough prevalence being higher.[97] Patients may describe this as a tickling sensation in the back of the throat that commonly occurs late in the evening. This is distinctly different from the cough associated with left ventricular dysfunction, which might be associated with crackles and rales (on auscultation) indicating possible pulmonary edema. ACEI-related cough resolves with discontinuation. Many agents have been used to treat an ACEI cough with poor results. The best treatment option for a patient with an intolerable ACEI cough is to switch agents.

CASE 9-5, QUESTION 8: How is an ARB different from an ACEI?

For A.R., switching to an ARB would likely eliminate the cough.[98] Although her first-choice antihypertensive should be CCB or thiazide diuretics, A.R. will also require the addition of a second agent, either a CCB or thiazide diuretic, because she has not achieved her goal BP of <130/80 mm Hg. ARBs are first line. There are eight ARBs (**Table 9-12**), and many are available as two-drug fixed-dose combination products.

Table 9-12
Angiotensin-Receptor Blockers in Hypertension

Drug	Starting Dose (mg/day)[a]	Usual Dosage Range (mg/day)	Dosing Frequency
Azilsartan medoxomil	80	80	Daily
Candesartan cilexetil	16	8–32	Daily to bid
Eprosartan mesylate	600	600–800	Daily to bid
Irbesartan	150	75–300	Daily
Losartan potassium	50	25–100	Daily to bid
Olmesartan medoxomil	20	20–40	Daily
Telmisartan	40	20–80	Daily
Valsartan	80–160	80–320	Daily

bid, two times daily.

[a]Starting dose may be decreased 50% if patient is volume depleted, very elderly, or taking a diuretic.

PHARMACOLOGIC DIFFERENCES BETWEEN AN ANGIOTENSIN-CONVERTING ENZYME INHIBITOR AND AN ANGIOTENSIN-RECEPTOR BLOCKER

Unlike ACEIs, ARBs specifically bind to angiotensin II receptors in vascular smooth muscle, adrenal glands, and other tissues. Access of angiotensin II to its receptors is blocked, and angiotensin I–mediated vasoconstriction and aldosterone release is prevented, resulting in BP reduction. ARBs do not affect bradykinin; therefore, dry cough does not occur.

Considerable investigation has focused on describing the pharmacologic differences between the angiotensin II type 1 and type 2 receptors. Stimulation of the type 1 receptor causes vasoconstriction, salt and water retention, and vascular remodeling. Other deleterious effects from type 1 receptor stimulation include myocyte and smooth muscle hypertrophy, fibroblast hyperplasia, cytotoxic effects in the myocardium, altered gene expression, and possible increased concentrations of plasminogen activator inhibitor. Stimulation of the type 2 receptor results in antiproliferative actions, cell differentiation, and tissue repair.

Case 9-5, Question 9: Under what circumstances would an ARB be a more appropriate initial antihypertensive agent than an ACEI?

Theoretically, an ideal antihypertensive agent would block only type 1 and not type 2 receptors as is the case with ARBs. Therefore, it is possible that an ARB would be superior to an ACEI in reducing hypertension-associated complications because ACEIs ultimately decrease stimulation of both type 1 and type 2 receptors by decreasing production of angiotensin II. This argument is purely speculative and is not supported by clinical trial data. *ON*going *T*elmisartan *A*lone and in Combination With *R*amipril *G*lobal *E*ndpoint *T*rial (ONTARGET) was a prospective, double-blind,

randomized controlled trial that directly compared ARB-based therapy, ACEI-based therapy, and the combination of an ACEI with an ARB.[99] After a median of 56 months, the incidence of CV events was no different among all three treatment groups. Therefore, ARB therapy is as effective as, but no more superior than, ACEI therapy in the overall management of hypertension.

Case 9-5, Question 10: If A.R. experienced angioedema from lisinopril, would treatment with an ARB be appropriate?

A history of ACEI-induced angioedema does not preclude the use of ARB therapy. The cross-reactivity between angioedema with an ACEI and ARB is not exactly known. The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity Alternative Study prospectively included patients with a history of ACEI intolerance who were randomly assigned, in a double-blind manner, to placebo or candesartan. Of the 2028 patients enrolled, 39 had a history of ACEI angioedema, and only 1 of these patients experienced repeat angioedema that required discontinuation of the ARB.[99] In the Telmisartan Randomised Assessment Study in ACE Intolerant Subjects with Cardiovascular Disease trial, 5926 patients with a history of ACEI intolerance were randomly assigned in this double-blind trial to an ARB or a placebo for a median duration of 56 months.[100] A total of 75 patients had a history of ACEI angioedema, and none of those patients who were randomly assigned to the ARB treatment arm experienced repeat angioedema. Therefore, cross-reactivity in angioedema between ACEIs and ARBs appears possible, but unlikely and very small. ARBs are an alternative for patients who experience ACEI angioedema but should be reserved for patients with a compelling indication for an ACEI. Of note, the ACC/AHA Guidelines recommend an ARB in patients who have experienced angioedema from an ACEI.[79]

Calcium Channel Blockers

CCBs effectively lower BP. Elderly and Black patients generally have greater BP reduction with a CCB than with other agents (β-blockers, ACEIs, and ARBs). The addition of a diuretic to a CCB provides additive antihypertensive effects. CCBs do not alter serum lipids, glucose, uric acid, or electrolytes.

All CCBs inhibit the movement of extracellular calcium, but there are two primary subtypes: dihydropyridines and nondihydropyridines (ie, diltiazem and verapamil). Each has distinctly different pharmacologic effects.

DIHYDROPYRIDINE CALCIUM CHANNEL BLOCKERS

Dihydropyridines are potent vasodilators of peripheral and coronary arteries. They do not block AV nodal conduction and do not treat arrhythmias. Moreover, the potent vasodilation associated with most dihydropyridines can induce a reflex tachycardia. With the exception of amlodipine and felodipine, dihydropyridines decrease cardiac contractility and should be avoided in patients with left ventricular dysfunction. Side effects of dihydropyridines are related to their potent vasodilatory effects (eg, tachycardia, headache, and peripheral edema).

Peripheral edema with CCB therapy, especially a dihydropyridine CCB, is a dose-dependent side effect. It is a direct result of the potent peripheral arterial vasodilation. When there is not equal vasodilation in the venous vasculature, a risk exists for leaking through the capillaries in the legs and, thus, an increased risk of peripheral edema. The best way to manage this side effect is to reduce the dose of the dihydropyridine or to add an agent that blocks the RAAS to decrease the effects of angiotensin II, which will result in a more balanced pressure gradient across her peripheral vasculature by providing vasodilation of both the arteries and veins. Adding either an ACEI or ARB can be used to accomplish this, with the added benefit of further lowering BP. Clinicians should note that using diuretics for the primary purpose of treating peripheral edema that is secondary to CCB use is not recommended and is not effective.

NONDIHYDROPYRIDINE CALCIUM CHANNEL BLOCKERS

The two nondihydropyridine CCBs, diltiazem and verapamil, are similar to each other. Relative to dihydropyridines, they are only moderately potent vasodilators, but they directly decrease AV nodal conduction and have greater decreases in cardiac contractility. The blockade of AV nodal conduction can slow heart rate and is the basis for their use in controlling supraventricular tachycardias associated with certain arrhythmias (eg, atrial fibrillation). Most patients only have a modest decrease in heart rate. However, heart block (first, second, or third degree) is a potential adverse effect, especially with large doses. Both diltiazem and verapamil should be avoided in patients with an underlying second- or third-degree heart block. Under these circumstances, a dihydropyridine can be used if a CCB is needed. Verapamil and diltiazem should be avoided in patients with left ventricular dysfunction because they can significantly reduce cardiac contractility. When patients with left ventricular dysfunction require a CCB to treat another condition (ie, angina or hypertension), amlodipine or felodipine may be used. They are the only CCBs that have been safely used in clinical trials of patients with left ventricular dysfunction. Unlike many other antihypertensive agents, they do not, however, protect against left ventricular dysfunction–related mortality. Diltiazem may have a lower incidence of constipation than does verapamil. Verapamil is also an effective agent in migraine prophylaxis and can be used if patients also have migraine. Patients with Raynaud phenomenon can obtain symptomatic relief from the peripheral vasodilation associated with a dihydropyridine CCB. Lastly, CCBs are effective in treating cyclosporine-induced hypertension, but should be used cautiously because verapamil and diltiazem increase cyclosporine concentration.

OTHER CONSIDERATIONS

Formulations

Several CCBs are available for the treatment of hypertension. They are listed in **Table 9-13**. Immediate-release formulations should be avoided (see Chapter 16, Hypertensive Crises).

Table 9-13
Calcium Channel Blockers in Hypertension[a]

Drug	Usual Dosage Range (mg/day)	Dosing Frequency
Nondihydropyridines[b]		
Diltiazem, sustained release	120–480	Daily
Diltiazem, extended release[c]	120–540	Daily
Verapamil, sustained release	180–480	Daily to bid
Verapamil, controlled-onset extended release[c]	180–480	qhs
Verapamil, chronotherapeutic oral drug absorption system[c]	100–400	qhs
Dihydropyridines		
Amlodipine	2.5–10	Daily
Felodipine, extended-release tablet	2.5–10	Daily
Isradipine, controlled-release tablet	5–20	Daily
Nicardipine, sustained-release capsule	60–120	bid
Nifedipine, sustained-release tablet[d]	30–90	Daily
Nisoldipine, extended-release tablet	17–34	Daily

bid, two times daily; qhs, every night.

[a]Immediate-release (IR) diltiazem, nifedipine, and verapamil should be avoided in hypertension.

[b]Many different long-acting products exist. Because their individual release characteristics vary, they are not exactly interchangeable using a milligram-per-milligram conversion.

[c]Chronotherapeutic agents are dosed primarily at bedtime and have a delayed drug release for a period of hours, followed by slow delivery of the drug that starts just before morning, with no delivery during the early evening; because they use different delivery systems, they are not interchangeable products.

[d]Only sustained-release nifedipine is approved for hypertension. Immediate-release nifedipine should be avoided for the management of hypertension.

Sustained-release formulations

CASE 9-6

QUESTION 1: C.F. is a 60-year-old male with hypertension, asthma, and type 2 diabetes. His hypertension is treated with HCTZ 25 mg daily and ramipril 20 mg daily for many years. Today, his BP is 148/74 mm Hg (144/72 mm Hg when repeated), and his heart rate is 90 beats/min. C.F.'s physician would like to add a CCB to his regimen to improve BP control.

What are the differences between controlled-onset, extended- release verapamil, and sustained-release verapamil? Are they interchangeable?

All CCBs have short half-lives, except amlodipine. Immediate-release forms require multiple daily doses to provide 24-hour effects. Sustained-released formulations are preferred when a CCB is used to treat hypertension. Various sustained-release delivery devices are available. Serum drug concentrations differ among sustained-release CCBs, but overall BP lowering is usually similar. Nonetheless, most of these products that include the same drug are not rated by the U.S. Food and Drug Administration as equivalent and identical. Insurance formularies often encourage therapeutic substitution between these agents. Therapeutic interchange between modified-release drug delivery formulations that allow for once- or twice-daily dosing (eg, sustained-release, extended-release, and chronotherapeutic products), however, are not equivalent using a milligram-per-milligram conversion. Therapeutic substitution among these products may result in variable BP-lowering effects if not adjusted appropriately. BP and heart rate monitoring should occur within 2 weeks of interchanging sustained-release CCBs.

CASE 9-6, QUESTION 2: Is there any clinical evidence on the use of CCB in diabetic outcomes?

CALCIUM CHANNEL BLOCKER AND DIABETES

CCBs have been shown to reduce risk of CV events in patients with diabetes,[99] although the evidence is not as convincing as that seen with an ACEI. The results of the Fosinopril versus Amlodipine Cardiovascular Events Randomized Trial and Appropriate Blood

Pressure Control in Diabetes Trial suggest that ACEIs have more CV protection than do CCBs.[58,59]

Nondihydropyridine CCBs (particularly diltiazem) may slow the progression of CKD, although evidence is not as extensive or definitive as it is with an ACEI or ARB. The proposed mechanism is dilation of both the afferent and efferent arterioles, which would decrease intraglomerular pressure. Dihydropyridines have unclear effects on progression of kidney disease. The prevailing opinion is that the renal protective effects of an ACEI and ARB are superior to that of a CCB.

Resistant Hypertension

CASE 9-7

QUESTION 1: R.R. is a 52-year-old male with hypertension for 10 years. He has not yet experienced any hypertension-associated complications or target-organ damage. He does not have a history of diabetes and does not smoke. He has been treated with HCTZ 25 mg daily, amlodipine 10 mg daily, valsartan 320 mg daily, and carvedilol 12.5 mg twice daily for 1 year. He reports rarely missing a dose of his medications, measures his BP at home every day, and follows recommended lifestyle modifications as diligently as possible. He has tried other medications that resulted in intolerances (doxazosin, dizziness; clonidine, dry mouth). His BP has never been <140/90 mm Hg, which is his goal. His BP today is 150/90 mm Hg (152/92 mm Hg when repeated), his heart rate is 60 beats/min, serum potassium is 4.2 mEq/L, and serum creatinine is 1.0 mg/dL. He is 72.04 inches (183 cm) tall and weighs 187.39 pounds (85 kg).

Does R.R. have resistant hypertension? What are his treatment options?

R.R. has resistant hypertension. If goal BP is not reached within a month of treatment of initial drug treatment, increase the dose of the initial drug or add a second drug from one of the first-choice classes of antihypertensives (thiazide diuretic, CCB, ACEI, or ARB). If goal BP cannot be reached with maximal tolerable doses of two drugs, add and titrate a third drug from the preferred drugs provided. Do not use an ACEI and an ARB together in the same patient. If goal BP cannot be reached using only the drugs in the preferred list, because

of a contraindication or the need to use more than three drugs to reach goal BP, then antihypertensive drugs from other classes can be used. Referral to a hypertension specialist may be indicated for patients in whom goal BP cannot be attained using the abovementioned strategy or for the management of patients with complications for whom additional clinical consultation is needed to rule out secondary causes of hypertension. R.R.'s treatment options are limited. Amlodipine and valsartan are both at the maximal doses. Carvedilol could be increased to 25 mg twice daily, but this should not be done because his heart rate is 60 beats/min and increasing this dose would place him at risk for bradycardia. It is possible to increase HCTZ to 50 mg daily because this higher dose provides larger BP reductions than does 12.5 or 25 mg daily based on 24-hour ABPM.[85] The limitation of this approach is an increased risk of electrolyte abnormalities and metabolic side effects.

Case 9-7, Question 2: How safe is it to add lisinopril 5 mg daily or spironolactone 25 mg daily in R.R.?

For resistant hypertension, three global treatment philosophies should be considered: (a) assuring appropriate diuretic therapy, (b) appropriate use of effective drug combination, and (c) use of alternative antihypertensive agents as appropriate.[15] Adding an ACEI to an already maximum dose of valsartan would not be recommended. The combination of an ACEI and ARB overall is not very beneficial. This combination should not be used specifically for the purpose of BP lowering, especially in primary prevention patients. When this combination was evaluated in the ONTARGET, the ACEI with ARB combination treatment arm provided only minimal additional reduction in BP compared with either agent alone and, most importantly, did not additionally lower risk of CV events. Moreover, there was a higher risk of adverse events (eg, kidney dysfunction and hypotension) with the combination arm.

The combination of an ACEI with ARB has been used in patients with left ventricular dysfunction based on promising data of a

reduced risk of heart failure hospitalizations.[101,102] However, the overall clinical benefits of an ACEI with an ARB versus an ACEI without an ARB are very small; addition of an aldosterone antagonist is the preferred next step in patients with left ventricular dysfunction who are already treated with the standard regimen of a diuretic, ACEI, and a β-blocker.[79] One potential niche for the use of an ACEI with an ARB is in the setting of CKD with significant proteinuria (300 mg albumin/day or 500 mg protein/day or per gram of urinary creatinine), in which the combination of an ACEI with an ARB seems to reduce progression of proteinuria better than either drug alone.[74]

Many patients with resistant hypertension have a significant component of volume expansion. Detecting this may not be easily observed using routine clinical examinations. However, identifying occult volume expansion using serial hemodynamic measurements from noninvasive bioimpedance testing, followed by enhancing diuretic therapy, has been shown to reduce BP better than did treatment selected by an experienced hypertension specialist.[103] Options to assure appropriate diuretic therapy include switching diuretic agents, switching diuretic classes, increasing the dose, or adding a different class of diuretic. Instead of increasing HCTZ to 50 mg daily, switching HCTZ to the more long-acting chlorthalidone is another possible option to enhance BP lowering. This is an option in R.R.'s case. Another option is switching HCTZ to a loop diuretic (eg, furosemide or torsemide). This should be considered for patients with stage 4 or 5 CKD (GFR <30 mL/min/1.73 m^2) or for those who need diuresis because of edema. This is not a reasonable treatment option for R.R. because he does not have CKD. Another option is to add an aldosterone antagonist, which is considered an alternative antihypertensive agent.[104] Patients with resistant hypertension often require the use of an agent(s) (**Table 9-14**) that is not widely used as either a first- or a second-line therapy. These therapies should not be used as monotherapy or a cornerstone of a multidrug regimen because there is less evidence to support their role in reducing CV events. It should be acknowledged, however, that some of these agents (eg, hydralazine) served as add-on agents to diuretics and β-blockers in early placebo-controlled, stepped-care approach trials in

hypertension. R.R. has already failed to fully respond to, or tolerate, several drug classes that typically are associated with reductions in hypertension-associated complications. To attain his BP goal of <140/90 mm Hg, an alternative agent, other than clonidine, should be selected because he did not tolerate it in the past.

Table 9-14

Alternative Antihypertensive Agents

Drugs/Mechanism of Action	Usual Dosage Range (mg/day)	Dosing Frequency
Aldosterone Antagonists (See Table 14-9)		
α_1-Blockers		
Doxazosin	1–8	Daily
Prazosin	2–20	bid to tid
Terazosin	1–20	Daily to bid
Direct Renin Inhibitor		
Aliskiren	150–300	Daily
α_2-Agonists (Central)		
Clonidine	0.1–0.8	bid
Clonidine	0.17–0.52	Daily
Clonidine transdermal	0.1–0.3	Once weekly
Methyldopa	250–1000	bid
Arterial Vasodilators		
Hydralazine	25–100	bid to tid
Minoxidil	2.5–80	Daily to bid

bid, two times daily; tid, three times daily.

ALTERNATIVE ANTIHYPERTENSIVE AGENTS

Aldosterone antagonists

Spironolactone and eplerenone are aldosterone antagonists that are especially useful as an add-on therapy in patients with resistant hypertension and would be a reasonable addition to R.R.'s

regimen.[10,104] Many patients with resistant hypertension have increased activation of the RAAS, which can result in increased aldosterone. Moreover, up to 20% of patients with resistant hypertension have primary aldosteronism.[10] These characteristics of patients with resistant hypertension make the addition of an aldosterone antagonist very effective in lowering BP in resistant hypertension.

R.R.'s potassium is in the normal range but could increase after adding spironolactone. Therefore, it should be monitored 2 to 4 weeks after therapy is started to assure that R.R. does not experience hyperkalemia. Eplerenone is more specific than is spironolactone in aldosterone blockade, although some data suggest that spironolactone is more effective in primary aldosteronism.[105] Compared with spironolactone, gynecomastia is less frequent with eplerenone. However, the incidence of hyperkalemia may be greater with eplerenone. When used for hypertension, eplerenone is contraindicated in populations at high risk for hyperkalemia including patients with an estimated creatinine clearance of <50 mL/min or elevated serum creatinine (>1.8 mg/dL in females and >2.0 mg/dL in males).

Case 9-7, Question 3: How beneficial would more intensive lifestyle modifications be in R.R.?

In addition to nonadherence to drug therapy, lifestyle factors (obesity, sodium ingestion, and heavy alcohol intake) are a significant contributor to resistant hypertension.[10] Lifestyle modifications should continually be reinforced in patients, especially those with resistant hypertension. As previously discussed, these modifications should include dietary changes and physical activity. R.R. should be instructed to restrict his daily sodium to <1.5 g because this has been shown to decrease SBP by >20 mm Hg in resistant hypertension.[25]

α-Blockers

CASE 9-8

QUESTION 1: J.L. is a 64-year-old male with hypertension. His BP is 158/84 mm Hg (156/86 mm Hg when repeated). His current antihypertensive regimen is HCTZ 25 mg daily, irbesartan 300 mg daily, and nifedipine extended release 60 mg daily. J.L. is not completely adherent to lifestyle modifications, but insists he is doing the best he can. He has been experiencing frequent nocturia, difficulty in starting urination, and a decrease in his urinary flow for the past several months and is diagnosed with benign prostatic hyperplasia (BPH).

J.L.'s physician is considering changing one of his antihypertensive agents to an α-blocker.

How do α-blockers compare with other agents in reducing CV events?

α-Blockers are not first-line agents in the management of hypertension. The ALLHAT study originally included an α-blocker (doxazosin) treatment arm.[50] Interim results after a mean follow-up of 3.3 years revealed that doxazosin had a statistically higher risk of combined CV disease and heart failure when compared with chlorthalidone.[106] Therefore, the ALLHAT data show that chlorthalidone was more effective in lowering some hypertension-associated complications than was doxazosin. This study did not include a placebo group; therefore, to conclude that doxazosin is harmful is inaccurate. For J.L., discontinuing HCTZ, irbesartan, or nifedipine to start an α-blocker is not prudent. It may be appropriate, however, to add an α-blocker to his regimen; an α-blocker will also have a benefit on his BPH (Table 9-7).

CASE 9-8, QUESTION 2: How can an α-blocker improve J.L.'s BPH?

The smooth muscle surrounding the prostate is innervated by α_1-receptors. By blocking these receptors, an α-blocker can improve the symptoms of BPH by reducing urethral tone and alleviating bladder outlet obstruction. Terazosin and doxazosin are both approved for the treatment of BPH. Prazosin should not be used because of the need for frequent dosing. Improvements in BPH symptoms with α-blockers are dose related. A high dose is often needed, and this increases the risk of side effects, such as orthostatic hypotension. In

J.L., an α-blocker will lower his BP and improve his urinary symptoms.

CASE 9-8, QUESTION 3: J.L. prefers to try doxazosin rather than undergo surgery to relieve his symptoms of BPH. How should this agent be started?

For J.L., it would be best to add a low dose of doxazosin to his present regimen. Based on his BP response and tolerance, the dose can be titrated up. One of his other antihypertensive agents can be decreased if he becomes hypotensive. The initial dose of doxazosin should not exceed 1 mg daily, and it should be given at bedtime. This can minimize orthostatic hypotension, which is the most frequent side effect of α-blockers. This complication is most pronounced with the first dose, but it can persist in some patients. Moreover, if an α-blocker is selected as add-on therapy in patients such as J.L. with resistant hypertension, nighttime administration of an α-blocker has been shown to be effective in further lowering BP.[107]

CASE 9-8, QUESTION 4: How should J.L. be counseled regarding side effects of doxazosin?

α-Blockers are well tolerated if dosed appropriately. J.L. could experience side effects, such as drowsiness, headache, weakness, palpitations from reflex tachycardia, and nausea, but these do not occur in all patients. Patients starting an α-blocker should be instructed to take the initial dose at bedtime and to anticipate the first-dose effect of orthostatic hypotension. Specifically, patients should be counseled to rise more slowly from a seated or supine position.

Miscellaneous Agents

ALISKIREN

CASE 9-9

QUESTION 1: R.P. is a 68-year-old male with hypertension and a history of ischemic stroke (1 year ago). Two months ago, his BP value was 164/94 mm Hg (162/98 mm Hg when repeated), with a heart rate of 62 beats/min while on sustained-release diltiazem 240 mg daily. He was started on benazepril/HCTZ 10/12.5 mg daily 2 months ago. His BP today is 142/82 mm Hg (144/82 mm Hg when repeated). All his laboratory values are normal except his serum creatinine, which is 1.9 mg/dL. J.L. has implemented lifestyle modification to the best of his ability.

His physician is wondering, should aliskiren be added to his drug regimen considering he is also on ACEI?

What kind of antihypertensive is Aliskerin?

DIRECT RENIN INHIBITORS

Aliskiren is a direct renin inhibitor. It inhibits the first step of the RAAS, which results in reduced plasma renin activity (PRA) and BP lowering.

CASE 9-9, QUESTION 2: How is aliskiren different from an ACEI or ARB?

This is different from the decreased production of angiotensin II with ACEIs and the blocked angiotensin II receptor effects with ARBs; however, BP-lowering effects are similar to those with ACEIs and ARBs. Aliskiren has a 24-hour half-life and, similar to most ACEIs and ARBs, is dosed once daily.

Some similarities and differences exist among the side effects associated with aliskiren when compared with ACEIs and ARBs. Aliskiren should not be used in pregnancy because of the known teratogenic effects from blocking the RAAS system. Increases in serum creatinine and serum potassium have been associated with aliskiren. These are similar to ACEI and ARB therapy and are mediated by the inhibition of angiotensin II vasoconstrictive effects on the efferent arterioles of the kidney and blocking of aldosterone. Monitoring of serum creatinine and serum potassium should be done in patients treated with aliskiren, particularly in those treated with the combination of aliskiren and an ACEI, ARB, potassium-sparing

diuretic, or aldosterone antagonist. Angioedema has also been reported in patients treated with aliskiren.

CASE 9-9, QUESTION 3: What is the role of aliskiren in treating R.P.'s hypertension?

The exact role of aliskiren in the treatment of hypertension is unclear. It is approved as monotherapy or in combination therapy. The BP reductions with aliskiren as monotherapy are similar to those seen with an ACEI, ARB, or CCB (specifically amlodipine). Aliskiren provides additive BP lowering when used in combination with HCTZ, ACEI, ARB, and CCB. However, its efficacy in combination with maximal doses of ACEI is unknown. Aliskiren is an alternative antihypertensive agent at this time because of the unknown long-term effects on CV events.

MIXED α-BLOCKERS AND NEBIVOLOL

Labetalol and carvedilol (**Table 9-15**) are nonselective β-blockers that also have an α_1-receptor blocking activity. Their antihypertensive effects are only somewhat similar to a combination of a nonselective β-blocker with an α_1-antagonist.

Table 9-15
Common β-Blockers in Hypertension

Drug	Usual Dosage Range (mg/day)	Dosing Frequency	Half-Life (hours)	β1-Selectivity	Lipid Solubility
Atenolol	25–100	Daily to bid	6–7	++	Low
Bisoprolol	5–20	Daily	9–12	+++	High
Carvedilol	12.5–50	bid	6–10	0	High
Carvedilol	10–80	Daily	6–10	0	High
Labetalol	200–800	bid	6–8	0	Moderate
Metoprolol tartrate	100–400	bid	3–7	+	Moderate to high
Metoprolol succinate	25–400	Daily	3–7	+	Moderate to high
Nebivolol	5–10	Daily	12–19	+++	High
Propranolol	40–180	Daily (LA and XL) or bid	3–5	0	High

bid, two times daily; LA, long acting; XL, extended release.

These agents produce vasodilation because of the α-blocker effects. The only other β-blocker that provides vasodilation is nebivolol. However, nebivolol produces vasodilation without blockade of α-receptors. The same precautions and contraindications relevant to nonselective β-blockers apply to both carvedilol and labetalol because they block both β_1- and β_2-receptors (Table 9-9).

Carvedilol is approved for both hypertension and left ventricular dysfunction. Carvedilol has been shown to reduce morbidity and mortality in a wide range of patients with left ventricular dysfunction.[108,109] Labetalol and carvedilol have no clear advantage over other β-blockers in most patients with hypertension, with the exception that they offer a dual mechanism of action within a single-drug formulation. In patients with type 2 diabetes, carvedilol has been shown to have no significant effect on glucose in comparison with metoprolol, which may slightly increase glucose.[110]

CENTRAL α_2-AGONISTS

The antihypertensive effects of α_2-agonists (Table 9-14) are attributed to their central α_2-agonist activity. Stimulation of α_2-receptors in the CNS inhibits sympathetic outflow (via negative feedback) to the heart, kidneys, and peripheral vasculature, resulting in peripheral vasodilation. Although the α_2-agonists effectively lower BP, they have many potential side effects and have not been evaluated in trials focused on CV events.

CASE 9-10

QUESTION 1: T.M. is a 43-year-old male. He is a truck driver with a 5-year history of hypertension. He does not have hypertension-associated complications. Secondary causes have been ruled out. His regimen is losartan/HCTZ 100/25 mg daily and sustained-release diltiazem 240 mg daily. Other antihypertensive drugs have failed because of various side effects (captopril and lisinopril, dry cough; atenolol and carvedilol, fatigue; nifedipine and amlodipine, edema; terazosin, orthostasis). T.M. has been adherent to his present medications and lifestyle modification, but has been unable to quit

smoking. His clinic values have been similar and averaged 150/95 mm Hg for the past 3 months. Clonidine 0.1 mg twice daily is added to his regimen.

What problems might occur if T.M. is not adherent to clonidine therapy?

Clonidine

α_2-Agonists are most effective when used with a diuretic because they all can cause fluid retention. Ideally, they should be used with agents that have different mechanisms of action and with agents that do not affect other central adrenergic receptors. Clonidine can cause rebound hypertension when abruptly stopped. T.M.'s occupation may place him at risk for this complication if he misses doses because of unusual work hours or prolonged travel.

Case 9-10, Question 2: How should T.M.'s clonidine dose be titrated?

Clonidine should be started at a low dosage and gradually increased to achieve optimal BP lowering with minimal side effects. The immediate-release tablet is started as 0.1 mg twice daily, with 0.1- or 0.2-mg/day increases every 2 to 4 weeks until his BP goal is achieved, or side effects appear. Clonidine is also available as an extended-release tablet and as a transdermal patch. The patch formulation releases the drug at a controlled rate for 7 days and may have fewer side effects than does the oral dosage form. The onset of initial BP effect may be delayed for 2 to 3 days after application; thus, rebound hypertension might occur when oral clonidine is switched to transdermal. To prevent this, an oral dose should be taken on the first day that the transdermal patch is used. Anticholinergic side effects, such as sedation and dry mouth, are the most frequent and bothersome side effects of clonidine. These are especially problematic in elderly patients.

Case 9-10, Question 3: After several months, T.M.'s BP is 148/84 mm Hg with clonidine 0.2 mg twice daily. However, he is now experiencing daytime somnolence and dry mouth. What other α_2-agonists are available?

Methyldopa

Methyldopa has been extensively evaluated and is considered safe in pregnancy. Therefore, it is recommended as a first-line agent when hypertension is first diagnosed during pregnancy.[111] Beyond that, little role exists for methyldopa in the management of hypertension. The usual initial dose is 250 mg administered twice daily up to 2000 mg/day. Methyldopa causes side effects similar to those associated with clonidine, including sedation, lethargy, postural hypotension, dizziness, dry mouth, headache, and rebound hypertension. These may decrease with continued use. Other significant side effects include hemolytic anemia and hepatitis. Although these are both rare, they necessitate discontinuing the medication.

Others

Guanfacine and guanabenz have a high incidence of side effects. These agents can cause dry mouth, sedation, dizziness, orthostatic hypotension, insomnia, constipation, and impotence, and are no longer commonly used. The adverse effects of other α_2-agonists (methyldopa, guanfacine, and guanabenz) are nearly identical to those of clonidine. In general, patients who do not tolerate one α_2-agonist will not tolerate the others. An antihypertensive agent from a different class (aldosterone antagonist, aliskiren, or an arterial vasodilator) should be chosen for T.M.

CASE 9-11

Question 1: C.M. is a 56-year-old female with a history of hypertension and severe CKD (eGFR of 14 mL/min/1.73 m^2). Her antihypertensive regimen consists of torsemide 40 mg daily, amlodipine/olmesartan 10/40 mg daily, and metoprolol succinate 200 mg daily. She started hydralazine 25 mg three times daily 4 weeks ago when her BP readings were 148/92 and 146/90 mm Hg. She has been very compliant, and her BP is now 146/88 mm Hg with a heart rate of 82 beats/min. Her lung fields are clear, with 1+ bilateral pitting edema. Serum electrolytes are within normal limits.

Why was hydralazine used in C.M.?

ARTERIAL VASODILATORS

Hydralazine

Hydralazine causes direct relaxation of arteriolar smooth muscle. Arterial vasodilators are infrequently used, except for patients with severe CKD. In this population, hypertension is difficult to control and often requires four or five agents. Severe CKD results in increased renin release and increased fluid retention. Potent vasodilation, in combination with diuresis, is often effective in lowering BP under these conditions. This vasodilation, however, stimulates the sympathetic nervous system and results in a reflex tachycardia, increased PRA, and fluid retention. Thus, the hypotensive effects of direct arterial vasodilators can quickly diminish with time when used as monotherapy. To prevent this, arterial vasodilators need to be used in combination with an agent that can slow down the heart rate (eg, β-blocker or nondihydropyridine CCB) to counteract reflex tachycardia, as well as a diuretic (often a loop diuretic if used in severe CKD) to minimize fluid retention.

CASE 9-11, QUESTION 2: After 18 months, C.M.'s hydralazine dose is 50 mg three times daily, and her BP is at goal. She now has joint pain in both hands, which extends to the wrists, and generalized weakness with frequent fevers. Laboratory findings for C.M. showed a positive antinuclear antibodies test (diffuse) result, a white blood cell count of 3500/μL, and an erythrocyte sedimentation rate of 45 mm/hour, and she is diagnosed with drug-induced lupus (DIL). How should this be managed?

C.M.'s symptoms are consistent with DIL. Hydralazine is one of the most common agents reported to cause DIL. Musculoskeletal pains are the most frequent symptoms, but systemic symptoms and rash may also occur. Hydralazine doses as low as 100 mg/day can cause DIL, and the risk significantly increases when >200 mg/day is used.

Hydralazine should be discontinued. Symptoms should subside within days or weeks, and complete resolution can be expected.

Case 9-11, Question 3: What alternatives to hydralazine are available for C.M.?

Minoxidil

C.M.'s BP responded to hydralazine, so she would likely benefit from another arterial vasodilator. Minoxidil, a potent arterial vasodilator, is similar to hydralazine with regard to reflex tachycardia, increased CO, increased PRA, and fluid retention. Therefore, concomitant β-blocker and diuretic therapy is still needed. Minoxidil should be reserved for patients such as C.M. who have severe CKD or possibly for resistant hypertension.

Case 9-11, Question 4: How should C.M. be counseled if minoxidil is started?

Hypertrichosis is a common adverse effect of oral minoxidil, occurring in 80% to 100% of patients. The hair growth is not associated with an endocrine abnormality and begins within the first few weeks. It commonly occurs on the temples, between the eyebrows, on the cheeks, and on the pinna of the ear. Hair growth can extend to the back of the legs, arms, and scalp with continued use. Some patients, especially females, find the hypertrichosis so intolerable that they stop treatment. Topical minoxidil is an approved therapy for male-pattern baldness, but topical administration does not provide BP-lowering effects.

Fluid retention with minoxidil is common, presenting as edema and weight gain. If adequate diuresis is not maintained during minoxidil therapy, left ventricular dysfunction may be precipitated or worsened. This also occurs with hydralazine. The compensatory reflex tachycardia with minoxidil may also precipitate angina in patients who have, or are at risk for, CAD.

Peripheral Vascular Disorders

Snehal H. Bhatt

CORE PRINCIPLES		CHAPTER CASES
1	Peripheral arterial disease (PAD) is stenosis or occlusion in the peripheral arteries of the legs, usually caused by atherosclerosis. A sometimes-painful complication called intermittent claudication (IC) can be associated with PAD and is described as aching, cramping, tightness, or weakness of the legs, which usually occurs during exertion.	**Case 10-1 (Question 1)**
2	Treatment for PAD should include therapeutic lifestyle changes and pharmacologic intervention based on risk factors present. Specific interventions may include smoking cessation; exercise; management of dyslipidemia, hypertension, and	**Case 10-1 (Questions 2–11)**

	diabetes; antiplatelet therapy; and verapamil.	
RAYNAUD PHENOMENON		
1	Raynaud phenomenon (RP) is an exaggerated vasospastic response to cold or emotion, likely mediated through sympathetic response to the precipitating stimuli. RP is classified as primary or secondary, in which secondary causes include connective tissue diseases and occupational-related neural damage.	**Case 10-2 (Question 1)**
2	Treatment for RP should include therapeutic lifestyle changes and pharmacologic intervention based on clinical presentation and underlying etiology. First-line interventions may include avoidance of cold stimuli and medications associated with vasoconstriction and treatment with calcium channel blockers. Several other therapies may be emerging as possible therapeutic options, including renin–angiotensin–aldosterone inhibitors, topical nitroglycerin, statins, peripheral α-adrenergic blockers, intravenous prostanoids, endothelin antagonists, and oral phosphodiesterase inhibitors.	**Case 10-2 (Questions 2–4)**

INTRODUCTION

Peripheral arterial disease (PAD) is a common and sometimes-painful complication from stenosis or occlusion in the peripheral arteries of the legs, usually caused by atherosclerosis. Similar to coronary artery disease (CAD) resulting in chest pain, PAD pain can be classified as “angina” of the legs. When closely comparing the risk factors and pathology of both the diseases, the association with CAD and intermittent claudication (IC) becomes clear.

IC is described as aching, cramping, tightness, or weakness of the legs, which usually occurs in the calves during walking and is relieved at rest. Tissue ischemia, resulting in numbness or continuous pain in the toes or foot, may be present and can lead to ulceration. IC is a painful condition that can severely limit mobility and lead to tissue necrosis or amputation of the affected limb. Many patients with PAD, however, are asymptomatic or have atypical lower limb symptoms, such as leg fatigue, difficulty walking, or similar nonspecific symptoms. Patients may not seek medical attention until the condition is advanced because of the gradual onset of symptoms associated with IC.

Epidemiology

PAD is a relatively common condition that affects males and females equally, with a prevalence of 12%,[1] although males have a twofold increased prevalence of symptomatic IC.[2] The annual incidence of IC increases dramatically with age (**Table 10-1**). Most patients with PAD are asymptomatic. In one study in which the prevalence of IC symptoms was 2%, only 11.7% of patients had detectable large-vessel atherosclerosis of the lower extremities.[3] This disparity between IC symptoms and the presence of PAD contributes to the observation that 50% to 90% of patients with IC do not mention PAD symptoms to their physician. Patients attribute the symptoms of IC to normal walking difficulties associated with aging, not a medical condition requiring treatment.[4] Public knowledge of the definition of PAD, risk factors for the development of the disease, associated symptoms and disease states, and amputation risk were evaluated

in adults older than age 50 years in a cross-sectional, population-based telephone survey. Unfortunately, only 25% of the population reported awareness of PAD.[5]

Table 10-1
Annual Incidence of Intermittent Claudication by Age

Age Group (years)	Annual Incidence (%)
40–49	2.0
50–59	4.2
60–69	6.8
70	9.2

Source: Caspary L. Epidemiology of vascular disease. *Dis Manage Health Outcomes.* 1997;2(suppl 1):9–17.

Risk factors for developing occlusive PAD are similar to those for CAD. Long-standing diabetes is the most significant risk factor, with 30% of patients with diabetes affected by PAD.[6] Each 1% increase in glycated hemoglobin is associated with a 28% risk of incident PAD.[7] Other atherosclerotic risk factors associated with PAD include cigarette smoking, hypertension, and dyslipidemia.[8] Hypertriglyceridemia is a more significant risk factor for PAD than for CAD, and this may partially explain the increased prevalence of PAD in patients with diabetes.[9]

Cigarette smoking is the strongest risk factor for PAD and the development of IC pain than any other risk factors, and the risk increases dramatically with the duration of smoking history and number of cigarettes smoked per day.[10] In patients with hypertension or diabetes, smoking further increases the rate of claudication development. Smoking confers a sevenfold increase in risk for PAD compared with not smoking.[11]

Epidemiologic studies following PAD patients over 4 to 9 years show that IC is nonprogressive in 75% of patients, whereas 25% of patients with IC will have worsening painful ischemic episodes. Ischemic tissue changes, ulceration, and gangrene can accompany advanced PAD. Amputation of the affected limb is rare, but can occur

in up to 5% of patients with claudication.[12] The presence of two independent risk factors, such as diabetes and cigarette smoking, has an additive effect on the risk for the development of progressive IC and serious limb complications (**Table 10-2**). Finally, disease location in patients with severe disease may be associated with prognosis. Proximal disease may be associated with poor outcomes when compared with distal lesions, although further studies are needed to confirm these findings.[13]

Table 10-2
Long-Term Incidence of Outcomes in Patients With Intermittent Claudication

Patient Population	Abrupt Limb Ischemia (%)	Amputation (%)
All patients	23	7
Diabetes	31	11
Smokers	35	21

Sources: McDaniel CD, Cronenwett JL. Basic data related to the natural history of intermittent claudication. *Ann Vasc Surg.* 1989;3:273–277; Hertzer NR. The natural history of peripheral vascular disease: implications for its management. *Circulation.* 1991;83(2 suppl):I12–I19.

During a relatively short 2-year follow-up of patients with IC, 3.6% of patients died, whereas 22% experienced a nonfatal cardiovascular event (defined as any cardiac, cerebral, or peripheral vascular event). Walking capacity declined in 26% during the same time frame; thus, it is paramount to recognize that severe, short-term morbidity is highly likely in this patient population.[14,15]

Pathophysiology

IC is the predominant complication of occlusive PAD because of the resulting pain and subsequent decreased mobility. The major cause of occlusive PAD is arteriosclerosis obliterans, defined as the development of atherosclerotic plaques in the peripheral vasculature. These plaques develop as a result of endothelial activation in

association with conditions such as dyslipidemia, diabetes mellitus, hypertension, and smoking. Plaques also result from the proliferation of vascular smooth muscle, with subsequent damage to the vascular structure. This damaged endothelium has impaired vasodilatory capabilities because secretion of nitric oxide is decreased and secretion of vasoconstrictive substances, such as endothelin, is increased, impeding blood flow to the extremities. Further growth of atherosclerotic lesions can physically limit blood flow. Exercise may induce IC symptoms in patients who have lesions with >50% stenosis, whereas patients with lesions of >80% stenosis can have pain at rest. The lesions themselves can become unstable and rupture, or adjacent smaller vessels experiencing high hemodynamic pressure caused by nearby plaques may rupture as well. Either situation can lead to acute vascular occlusion, analogous to unstable angina or acute myocardial infarction (MI) in coronary arteries.[16]

Figure 10-1 illustrates the common sites of atherosclerosis. Plaques that develop in central vessels (eg, in the aorta and iliac artery) are primarily associated with buttock pain and erectile dysfunction. Those confined to the more distal femoral and popliteal arteries characteristically cause thigh and calf pain. Occlusion of the tibial arteries will produce claudication pain in the foot. When more than one arterial bed is affected by severe atherosclerosis, symptoms of IC will be diffused. Symptoms of IC indicate an inadequate supply of arterial blood to peripheral muscles. Exercise, including walking, increases the metabolic demands of the muscles and can lead to claudication pain.

Erythrocyte deformability is an important factor for in vitro capillary perfusion.[17,18] In areas without compromised blood flow, normal red blood cells (RBCs) have the ability to deform when passing through a small capillary. By aligning themselves in a planar manner, RBCs reduce viscosity of the blood suspension, enabling them to pass smoothly through capillaries. In many patients with IC, RBCs have a marked decreased ability to deform, resulting in increased blood viscosity. This defect is promoted by chronic tissue ischemia and hypoxia caused by increased intracapillary leukocyte adherence, platelet aggregation, and activation of complement and clotting factors.[16] The vascular responses to hypoxia are detrimental because this sequence of events further inhibits blood flow and oxygen delivery to the tissues (**Fig. 10-2**).

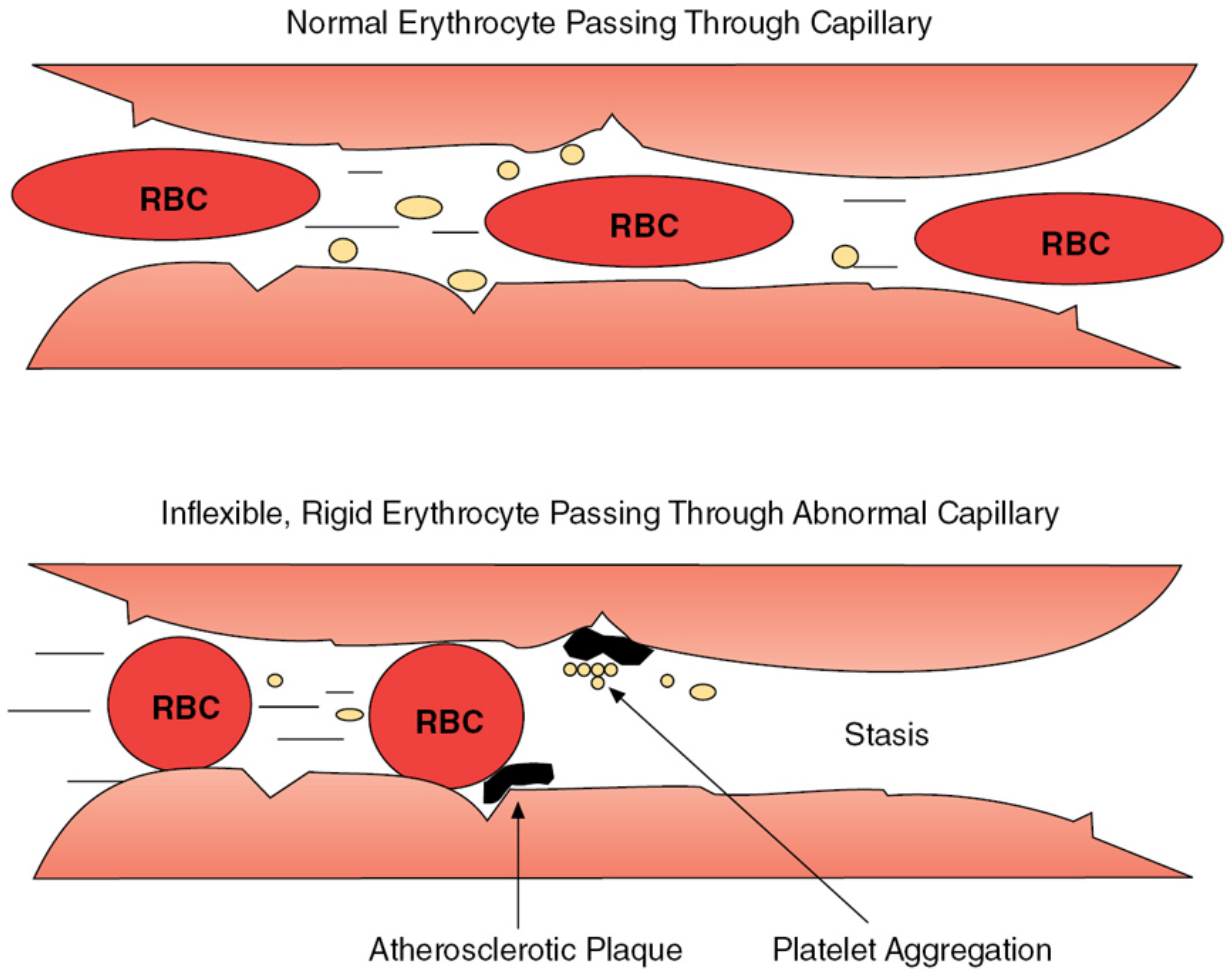

Figure 10-2 Erythrocyte inflexibility in intermittent claudication.

Clinical Presentation

CASE 10-1

Question 1: R.L. is a 60-year-old, 242.51-pound (110-kg) male with a history of type 2 diabetes mellitus, chronic stable angina, dyslipidemia, and smoking. He comes in today with right upper thigh pain while walking around the block. The pain has gradually increased during the past 12 months, but only recently has become intolerable. The pain is relieved within minutes after he stops walking. R.L. smokes two packs of cigarettes a day.

His most recent laboratory results are significant for the following results:

Total cholesterol, 290 mg/dL (SI units, 7.49 mmol/L)
Fasting triglycerides, 350 mg/dL (SI units, 3.95 mmol/L)
Low-density lipoproteins (LDLs), 188 mg/dL (SI units, 4.86 mmol/L)

High-density lipoproteins (HDLs), 32 mg/dL (SI units, 0.83 mmol/L)
Serum creatinine (SCr), 0.8 mg/dL (SI units, 61 mmol/L)
Blood urea nitrogen (BUN), 18 mg/dL (SI units, 6.4 mmol/L)
Hemoglobin (Hgb) A_{1c}, 8.2% (SI units, 10.5 mmol/L)
Fasting glucose, 175 mg/dL (SI units, 9.64 mmol/L)
Blood pressure (BP), 170/95 mm Hg
Heart rate (HR), 89 beats/minute
His posterior tibial artery pulse is not palpable. A Doppler ultrasound study is performed, and his ankle–brachial index (ABI) is 0.7 (normal, >0.90). R.L.'s medication list includes isosorbide mononitrate 60 mg daily, aspirin 81 mg daily, and ramipril 5 mg daily. His metformin doses have progressively increased to 1000 mg twice daily.

What risk factors and elements of R.L.'s presentation are consistent with a diagnosis of IC?

R.L.'s medical history illustrates classic risk factors for vascular occlusion and IC, including dyslipidemia, diabetes, hypertension, and smoking. His diabetes is not adequately controlled based on elevated A_{1c} and fasting glucose levels, and he is obese. This constellation of disorders is known as *metabolic syndrome.* These factors, along with smoking, are commonly seen together and have been linked with insulin resistance and accelerated atherosclerosis (**Fig. 10-3**).[19,20] The presence of angina indicates CAD, so it is not surprising that he has peripheral vascular occlusion as well.

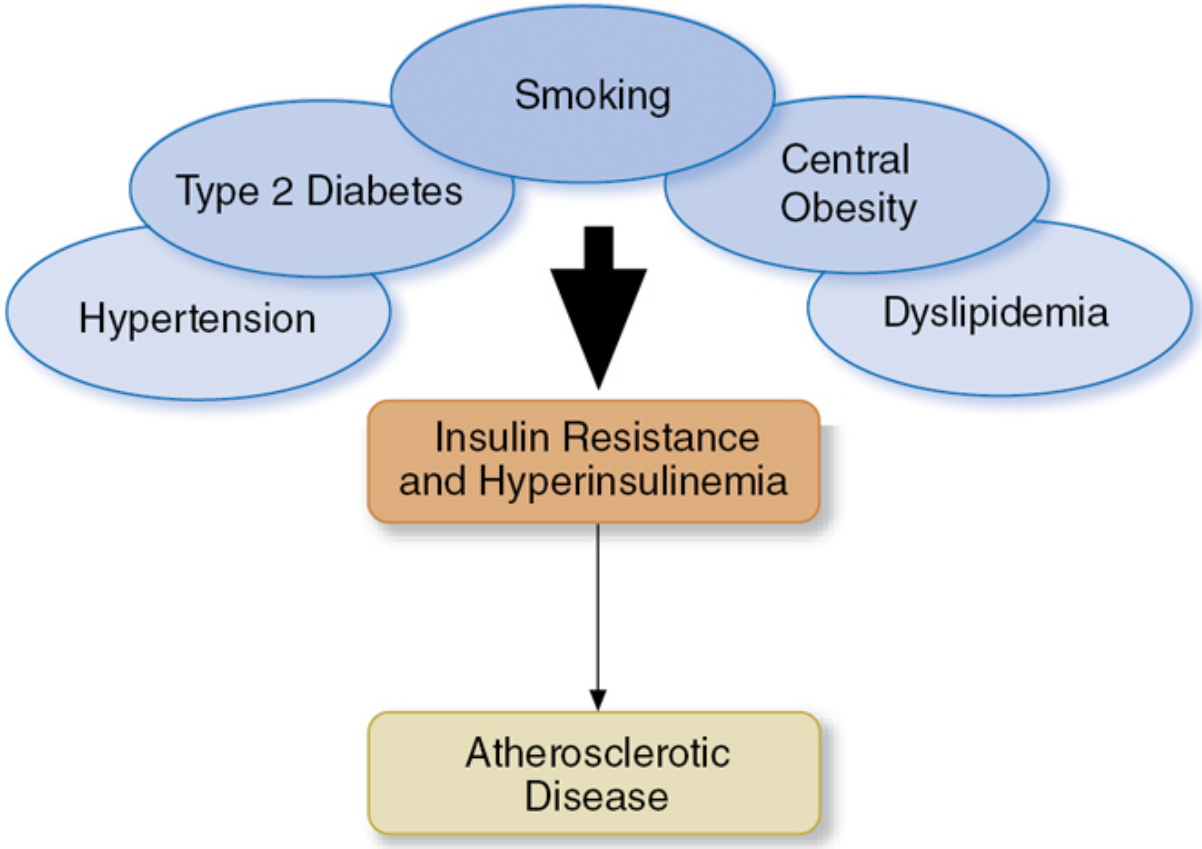

Figure 10-3 The metabolic syndrome in atherosclerosis.

The classic pain of IC described by R.L. is associated with exercise of the affected muscle group(s) and subsides with a few minutes of rest. Other common symptoms of extensive atherosclerosis include cold feet and persistent aching of the feet during rest or sleep. Restricted blood flow to the feet along with pooling of blood secondary to inadequate pressure needed to propel blood back up the leg can lead to rubor (red or purple color of the foot). Other indicators of peripheral atherosclerosis are the loss of hair from the top of the feet, thickening of the toenails, and absence of sweating of the lower legs and feet, all caused by poor circulation.[16]

The results of objective studies performed on R.L. are consistent with IC. Doppler ultrasound of the spine is helpful in excluding pseudoclaudication caused by spinal stenosis and other neurogenic or musculoskeletal causes of leg pain. Ultrasound is also useful to

measure BP of the lower extremities. An ABI of 0.7 means that the ankle systolic BP reading is only 70% of the systolic pressure in the brachial artery supplying blood to the arm. In patients with IC, this is caused by atherosclerotic obstruction of blood flow in the lower limbs and subsequent decreased perfusion pressures in the ankle compared with the arm (**Table 10-3**). As the ABI decreases, blood flow to the extremities is reduced and the severity of symptoms is greater. An ABI <0.9 is diagnostic for PAD. Loss of the posterior tibial pulse, as seen in R.L., is common in those with peripheral vascular occlusion.

Table 10-3
Severity of Arterial Obstruction as Assessed by Ankle–Brachial Index

Severity	Ankle–Brachial Index[a]
Normal	>0.90
Mild	0.70–0.89
Moderate	0.50–0.69
Severe	>0.50

[a]Ankle–brachial index is the systolic blood pressure in the ankle divided by the systolic blood pressure in the arm.

Treatment

THERAPEUTIC OBJECTIVES AND NONPHARMACOLOGIC INTERVENTIONS

CASE 10-1, QUESTION 2: What are the therapeutic goals in treating R.L.? What interventions should be initiated to prevent claudication pain and arrest progression of his disease?

Specific treatment goals include preventing further claudication pain, lessening his current pain, arresting the progression of

underlying disease, and decreasing his risk of cardiovascular events. Achieving these goals will provide R.L. with the best chance of avoiding further mobility impairment, amputation, and cardiovascular events. An important concept that should be stressed when explaining these treatment goals to R.L. is that all his diseases are closely interrelated and that a beneficial intervention for one disease is beneficial for all. Interventions that can be initiated include diet modification; exercise and weight loss; and attainment of goal BP, lipids, Hgb A_{1c}, and fasting and postprandial blood glucose levels. The American College of Cardiology and American Heart Association (ACC/AHA) have published guidelines that thoroughly evaluate the interventions and medications that have been used to treat IC and PAD.[8] **Table 10-4** summarizes these recommendations. The two most important things that R.L. can do for his IC are summed up in five words: "Stop smoking and keep walking."[21]

Table 10-4

Medical Treatment of Peripheral Arterial Disease and Expected Outcomes

Intervention	Improve Leg Symptoms?	Prevent Systemic Complications?
Smoking cessation	Yes	Yes
Exercise	Yes	No
Cilostazol	Yes	No
Statin drugs	Yes	Yes
Angiotensin converting enzyme inhibitors	Yes	Yes
Blood pressure control	No	Yes
Antiplatelet therapy[a]	No	Yes

Smoking cessation

The importance of smoking cessation cannot be overemphasized to patients with IC. It is the most important modifiable factor in preventing the development of rest pain, prolonged limb ischemia, need for amputation, and reducing the risk for cardiovascular events. Several studies document improved survival and decreased amputation rates in patients with IC who stopped smoking compared with patients who continue to smoke.[22,23] Other benefits, such as improved treadmill walking distance, decreased disease progression, and decreased complications after vascular reconstructive surgery, have been shown in patients who quit smoking compared with patients who continue.[8,22,24–27] It is the one intervention that will decrease R.L.'s claudication pain most rapidly. He will also decrease his risk of MI and mortality by threefold and fivefold, respectively. **Table 10-5** summarizes the risk of cigarette smoking and the value of smoking cessation on cardiovascular complications.

Table 10-5
Patient Outcomes Based on Smoking Status After Intermittent Claudication Diagnosis

Outcome	Length of Follow-Up (years)	Patient Population	
		Current Smokers (%)	Past Smokers (%)[a]
Rest pain	7	16	0
Myocardial infarction	10	53	11
Amputation	5	11	0
Mortality	10	54	18

Cessation of smoking in patients with intermittent claudication: effects on the risk of peripheral vascular complications, myocardial infarction, and mortality. *Acta Med Scand.* 1987;221:253–260.

Many pharmacologic products and strategies are available to aid R.L. to stop smoking (see Chapter 91, Tobacco Use and Dependence). However, nicotine itself has harmful effects on the vasculature via catecholamine release and vasoconstriction, and it may play a role in endothelial damage and atherosclerosis progression.[28]

Exercise

An individualized and supervised exercise program is endorsed for patients with PAD and will benefit most of R.L.'s other risk factors as well.[8,24] IC pain results in decreased mobility, and because of deconditioning from lack of exercise, patients with IC may slowly become dependent on others for activities of daily living. An exercise program is the most effective way to both preserve and increase mobility. It is more effective than the best pharmacologic therapy currently available.[29] The ideal exercise program consists of walking for a minimum of 30 to 45 minutes at least three times a week, for a minimum of 12 weeks.[8] R.L. should walk as fast and far as he can until the pain becomes severe; he should then wait until the pain subsides, and then resume walking.[30] At first, R.L. may experience several painful episodes during each exercise session, but these should gradually decrease as the beneficial effects of exercise therapy begin to emerge. Studies have documented that this type of exercise program can more than double the pain-free distance a patient with IC is able to walk.[31] Lower extremity resistance training can provide improved functional performance measured by the following: quality of life, treadmill walking time, and ability to climb stairs.[32] An appropriate exercise program results in superior outcomes compared with angioplasty and stenting, and equal in

terms of walking distance compared with surgery, but without any of the significant complications and mortality associated with surgery.[31]

Rheologic abnormalities of increased blood viscosity, impaired RBC filterability, hyperaggregation, and polycythemia (elevated hematocrit) have been shown to return to normal in many patients with IC who participate in a regular exercise program.[33] Exercise may offset the need for pharmacologic intervention. The potential mechanisms by which exercise benefits patients with IC are listed in **Table 10-6**.

Table 10-6
Primary Mechanisms of Symptom Improvement With Exercise Therapy in Intermittent Claudication

Decrease of blood viscosity
Metabolic changes in the muscle
Improved muscle metabolism
Improved oxygen extraction
Improved endothelial function and microcirculation
Decreased occurrence of ischemia and inflammation
Atherosclerosis risk factors improved via

Dyslipidemia management

Case 10-1, Question 3: Is lipid-lowering therapy indicated for R.L.?

Because IC is a consequence of atherosclerosis, arresting the progression of R.L.'s atherosclerotic disease is important (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). Initiation of the nutritional and exercise recommendations

should be recommended as outlined in the 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease[34] and endorsed by the 2018 AHA/ACC/AACVPR/AAPA/ABC/ACPM/ADA/AGS/APhA/ASPC/NLA/PCNA Guideline on the Management of Blood Cholesterol.[35] Therapeutic lifestyle changes and cholesterol-lowering agents are the cornerstones for attaining this goal. Considerable data suggest that aggressive dietary and pharmacologic management of dyslipidemia, particularly lowering low-density lipoprotein cholesterol (LDL-C), leads to regression of atherosclerotic lesions in the coronary and carotid vasculature.[36–38] In contrast, relatively few prospective data exist about the effect of successful lipid-lowering therapy on the regression or stabilization of peripheral lesions, or on clinical events in patients with PAD. A post hoc analysis of a large lipid-lowering study in subjects with known CAD treated with simvastatin demonstrated a significant decrease in new or worsening IC, suggesting that in high-risk patients, lipid lowering can prevent development of clinically symptomatic PAD.[39] The Heart Protection Study randomly assigned patients with known arterial disease of various types to simvastatin 40 mg daily or placebo. After 5 years, a 15% decrease was found in noncardiac revascularizations, including amputations, among the patients receiving simvastatin.[40] Short-term outcomes (eg, 6 months–1 year), such as improved walking distance and walking time, have also been documented with simvastatin 40 mg/day.[41,42]

A meta-analysis of 10,049 subjects from several randomized trials using a variety of lipid-lowering therapies in patients with PAD demonstrated reduced claudication severity and decreased disease progression as measured by angiography. A decrease in mortality did not reach statistical significance.[43] Limited data suggest that high apolipoprotein [Lp(a)] concentrations may be particularly important in the development of PAD.[44]

Patients with PAD fall into one of the four major statin benefit groups, specifically falling into the group with known atherosclerotic cardiovascular disease (ASCVD). Because R.L. is <75 years old, he warrants high-intensity statin therapy, which is defined as statin

therapy at doses that are expected to provide at least a 50% reduction in LDL cholesterol (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). There is a paucity of outcome data with other agents for dyslipidemia, as trials of ω-3 fatty acid, niacin, or fibric acid derivative have failed to demonstrate a reduction in cardiovascular events in patients with increased risk for cardiovascular events like R.L.[8,24,34,35,45–48]

Case 10-1, Question 4: R.L.'s BP is elevated to 170/95 mm Hg despite ramipril therapy. Because he has angina, and his HR is 89, a β-adrenergic blocker is considered. Are there alternative antihypertensive therapies that might be preferable for R.L.?

Management of hypertension

R.L.'s hypertension has likely contributed to the development of his atherosclerosis and PAD. Hypertension (see Chapter 9, Essential Hypertension) has been associated with deficiencies in the synthesis of vasodilating substances, such as prostacyclin, bradykinin, and nitric oxide, by the endothelial cells lining the vasculature, along with increases in vasoconstricting substances like angiotensin II. Increased vascular tone can alter local hemodynamics, especially in the presence of a stenotic lesion. Although it has not been determined whether normalization of BP has a positive effect on IC, it is well established that uncontrolled BP results in vascular complications such as MI and stroke. In light of R.L.'s numerous risk factors for these complications, improvement in his BP is warranted.

β-Blockers are frequently cited as contraindicated in IC patients owing to the potential for unopposed α-adrenergic-mediated vasoconstriction during peripheral β-blockade. However, evidence to document worsening IC by β-blockade is lacking. Overall, controlled studies have been inconclusive, and a meta-analysis of placebo-controlled trials and studies with control groups concludes that β-blockers do not worsen claudication.[49,50]

Angiotensin converting enzyme (ACE) inhibitors are first-line agents in patients with PAD.[8,24] Compared with other

antihypertensive agents, the data available support their beneficial effects in this population. Compared with placebo, walking distance is increased with both perindopril and ramipril in patients with PAD.[51,52] The Heart Outcomes Prevention Evaluation (HOPE) study compared ramipril versus placebo in over 9000 patients who had evidence of vascular disease or diabetes. Impressively, they enrolled more than 4000 patients with PAD, and similar to the overall trial population, patients with PAD derived a benefit in the composite end point of decreased mortality, MI, and stroke.[53] The ONTARGET trial compared telmisartan, ramipril, and the combination of the two in patients with vascular disease or high-risk diabetes without heart failure for a composite end point of cardiovascular death, MI, stroke, or hospitalization for heart failure. The results suggested equivalency of telmisartan to ramipril for the primary end point with similar BP reduction in both groups; however, the combination therapy group experienced more adverse events without any benefit.[54] Based on these data, ARBs may be a suitable substitute for ACE inhibitors, but combination therapy is not recommended.

R.L.'s. BP goal is <130/80 mm Hg.[55–57] His dose of ramipril could be increased, or a low-dose diuretic, such as hydrochlorothiazide or chlorthalidone,[55,56] could be added. Given his history of chronic stable angina, the addition of a calcium channel blocker (CCB) or a β-blocker would be an option as well. The ACCOMPLISH trial compared the combination of benazepril–amlodipine with benazepril– hydrochlorothiazide in patients with hypertension who were at high risk for cardiovascular events. Amlodipine therapy reduced cardiovascular events compared with hydrochlorothiazide, even though BP control was not significantly different.[58] Although β-blockers are typically used in patients with CAD, the outcome data supporting their use are less clear.[59]

Management of diabetes

Case 10-1, Question 5: Will improving R.L.'s diabetes control or slow the progression of his PAD? What changes in his diabetes management do you

recommend?

Patients with type 2 diabetes mellitus (see Chapter 53, Diabetes Mellitus) are able to minimize macrovascular and microvascular complications of their disease with aggressive glucose control.[7,60,61] Historically, insulin, sulfonylurea, or metformin therapies have a beneficial effect on slowing the development of the microvascular complications of diabetes, such as retinopathy and nephropathy. Metformin has specifically been shown to further reduce the occurrence of macrovascular complications such as stroke or MI compared with insulin or sulfonylureas in obese patients with type 2 diabetes,[60] whereas recent data with sodium-glucose co-transporter-2 (SGLT-2) inhibitors and glucagon-like peptide 1(GLP-1) agonists have demonstrated significant reduction in ASCVD risk and have been given priority status for reducing ASCVD risk in patients with type 2 diabetes.[62]

R.L.'s diabetes is a significant risk factor for progression to further ischemic events (**Table 10-7**). He has a twofold greater risk of death and a sevenfold greater risk of amputation compared with a patient without diabetes. Although a specific benefit for IC has not been demonstrated, it seems prudent to initiate or continue aggressive diabetes management in patients with type 2 diabetes mellitus and IC. In addition to metformin, addition of either an SGLT-2 inhibitor or GLP-1 agonist to R.L.'s therapy would improve his blood glucose control and decrease his risk of ASCVD. It is hoped that R.L. can reach his Hgb A_{1c} goal of <7% and a fasting blood glucose of 80 to 130 mg/dL and 2-hour postprandial glucose of <180 mg/dL with diet and exercise, while adding metformin to his current therapy.[62,63]

R.L. also must take proper care of his feet to prevent ulcerative complications of IC. He should be encouraged to keep his feet warm, dry, and moisturized and to wear properly fitted shoes and perform daily foot inspections.[8] He should seek medical attention immediately for minor trauma to his feet or legs.[4] These measures can reduce the incidence of amputation in patients with diabetes.

PHARMACOLOGIC THERAPIES

Antiplatelet therapies

Case 10-1, Question 6: Is R.L.'s aspirin therapy beneficial for preventing further complications of IC? Would alternative antiplatelet therapies offer advantages over aspirin?

Aspirin is one of several antiplatelet agents that may be considered for indefinite use in patients with PAD. There is limited data on the effects of aspirin on IC symptoms. Whether aspirin has any beneficial effects on walking distance or claudication pain has not been studied. Available data address the impact of aspirin on overall cardiovascular morbidity and mortality. Although aspirin has no direct effect on plaque regression, it does prevent and retard the role platelets play in the thrombogenic events that occur in the vicinity of atherosclerotic plaques.[64] Aspirin is an effective antithrombotic agent at dosages ranging from 50 to 1500 mg daily. The lowest dosages proven to decrease cardiovascular events are 75 to 100 mg daily,[65] with the higher dosage showing benefit in active processes, such as acute ischemic stroke[66] and acute MI.[67] A dosage of 75 mg daily has demonstrated benefit in patients with hypertension[68] and stable angina.[69] No evidence indicates that these

“low doses” are any more or any less effective than dosages of 900 to 1500 mg daily.[70]

Aspirin is recommended in patients with vascular disease of any origin (stroke, MI, PAD). At dosages of 75 to 162 mg/day, aspirin decreases vascular death by ~15% and all serious vascular events (MI, stroke, or vascular death) by ~20% in high-risk patients, including those with PAD.[62,65,69] In patients with PAD, aspirin can delay the progression of established lesions as assessed by angiography. When used for primary prevention of cardiovascular disease in males, aspirin decreased the need for arterial reconstructive surgery, which was needed because of PAD.[71] In a meta-analysis of 5269 subjects with PAD, aspirin was associated with a significant reduction in nonfatal stroke with a statistically insignificant decrease of cardiovascular events.[72] However, in a recent large randomized, controlled trial in 3350 patients ages 50 to 75 years without clinically evident cardiovascular disease but with a screening ABI of 0.95 or less, aspirin 100 mg/day was found to be no more effective than placebo in reducing the primary end point of fatal and nonfatal coronary events, stroke, or revascularization (13.7 events per 1000 person-years in the aspirin group vs 13.3 in the placebo group; hazard ratio, 1.03; 95% confidence interval, 0.84–1.27).[73]

Because all dosages of aspirin are similarly efficacious in decreasing vascular events in this patient population, side effects influence the dose chosen. Although few studies have directly compared varying doses, side effects appear to be dose related. Aspirin 30 mg daily results in less minor bleeding compared with ~300 mg daily,[74] and 300 mg daily results in fewer gastrointestinal (GI) side effects compared with 1200 mg daily.[75] Therefore, R.L. should take the lowest effective dose of aspirin: 75 to 100 mg daily. Of note, R.L.’s hypertension should be controlled before initiating aspirin therapy to decrease the small increased incidence of cerebral hemorrhage associated with its use.[76]

Ticlopidine is the first thienopyridine derivative that blocks adenosine 5′-diphosphate (ADP) receptors on platelets and decreases platelet–fibrinogen binding.[77] Several studies document

its efficacy in patients with PAD on end points such as walking distance, cardiovascular death, and the need for revascularization surgery.[78,79] However, hematologic toxicities (neutropenia and, rarely, thrombotic thrombocytopenic purpura) limit its use.[80,81]

Clopidogrel initially replaced ticlopidine largely because of its improved safety profile. The effects of clopidogrel on specific PAD outcomes are unknown, but it has been compared with aspirin in patients with known atherosclerotic disease. Dosages of 75 mg daily significantly reduced cardiovascular end points by ~25% compared with aspirin in this patient population.[82] The treatment effect was most pronounced in the PAD subgroup, leading to the suggestion that clopidogrel may be preferable in the patient population with PAD. No measure was taken of clopidogrel's effect on walking distance or claudication pain, however, and these results have not been confirmed by further studies.

The combination of aspirin and clopidogrel was compared with aspirin alone in more than 15,000 patients at high risk of vascular events, of whom >20% had a history of PAD and ~10% had IC.[83,84] In this large study that assessed cardiovascular end points, no benefit was found for dual antiplatelet therapy with aspirin plus clopidogrel.[80] Thus, although clopidogrel has the same guideline recommendation as aspirin, clinically it is often used as an appropriate alternative to aspirin in patients unable to take aspirin therapy,[65] perhaps owing to a serious allergy.[8] It should not be used in addition to aspirin, however, because the risk of bleeding and increased cost outweigh any measurable vascular benefit.[84,85]

Ticagrelor was compared with clopidogrel in 13,885 patients with known symptomatic PAD but without documented CAD.[86] There was no difference between the two groups with regard to the primary composite end point of death, MI, and stroke. Ticagrelor was discontinued more frequently than clopidogrel because of the occurrence of side effects (dyspnea and minor bleeding). Based on these data, ticagrelor cannot be recommended to reduce the risk of cardiovascular events in PAD patients at this time. These data also question whether there are differences in cardiovascular risk in patients with both CAD and PAD versus those with PAD alone.

Case 10-1, Question 7: Are there any medications that can be used to increase the walking abilities of patients with IC?

Cilostazol

Cilostazol is one of the few agents approved by the U.S. Food and Drug Administration (FDA) specifically for the treatment of IC. Several studies have confirmed that cilostazol 100 mg twice daily increases walking distance by ~50%[87–90] and that discontinuation of cilostazol results in a decline in function.[91] Cilostazol possesses antiplatelet and vasodilatory effects mediated by the inhibition of phosphodiesterase III.[92] In vitro observations suggest that these pharmacologic effects of cilostazol are particularly pronounced at the blood–vessel interface,[92] which may explain its particular efficacy in the patients with PAD. Studies that included quality-of-life measurements have found that cilostazol improved overall quality of life.[87,93] Small improvements in ABI with chronic cilostazol therapy have also been observed.[94] Two small studies indicate cilostazol is associated with a reduction in restenosis after endovascular therapy in femoropopliteal lesions.[95,96]

Despite these positive findings with cilostazol, several drawbacks exist. It is contraindicated in patients with heart failure based on data with other phosphodiesterase inhibitors demonstrating excess mortality, presumably because of increased arrhythmias.[97] Other common side effects include headache, occurring in up to one-third of patients, and loose stools or diarrhea.[88,98] Cilostazol is a cytochrome P-450 3A4 substrate; therefore, any inhibitor of this enzyme system may substantially increase cilostazol concentrations.

Cilostazol is an important advancement in the treatment of IC. It is the first pharmacologic agent to demonstrate a consistent effect on a significant source of IC disability: walking and mobility measures. Although limited data address its impact on other important end points, such as amputation and revascularization procedures or cardiovascular events,[99] it should be added to R.L.'s existing medication regimen at a dosage of 100 mg twice daily to attenuate his symptoms of IC.

Rheologic agents

Case 10-1, Question 8: Has pentoxifylline been shown to be efficacious in patients such as R.L.? How does this drug benefit patients with IC?

Pentoxifylline, a methylxanthine derivative, is another agent approved by the FDA for the treatment of IC. Pentoxifylline appears to decrease blood viscosity by decreasing fibrinogen, improving the deformability of both red and white blood cells, and eliciting antiplatelet effects, although the exact mechanism of action is unclear.[100] Although the theoretic and in vitro data are unique and positive, data demonstrating its clinical usefulness are controversial. Improvements in walking distances from study to study are unpredictable, and the clinical importance of the sometimes minimal increases in walking distances is not clear (eg, pain-free walking of ~30 m greater than with placebo).[101] Some experts assert that these potential benefits of questionable clinical significance are not worth the expense of drug therapy or the GI side effects.[102]

Pentoxifylline's role in IC therapy is limited. It may have a role in patients who are unable to engage in exercise therapy, or in patients with markedly reduced walking distances, or in whom any small increase in walking distance would greatly improve a patient's activity level.[103] It also may be tried in patients who have not gained the desired benefit from smoking cessation and exercise therapy and in patients with contraindications, intolerance, or failure of cilostazol. A 2-month trial of pentoxifylline is adequate to determine whether the patient will benefit from therapy.[30] R.L. is not severely debilitated, and the benefits of smoking cessation, exercise therapy, and cilostazol have not been fully realized. Therefore, pentoxifylline should not be added until his response to these well-proven therapies has been determined and the need for further improvement in walking distance is established.

Vasodilators

Case 10-1, Question 9: R.L. is already taking isosorbide mononitrate for angina. Because IC is made worse by vasoconstriction, should another vasodilating agent be added to treat both his hypertension and IC?

The use of vasodilators for R.L. would at first appear to be a logical pharmacologic intervention to prevent claudication pain. Vasodilators, including isosorbide, directly or indirectly relax blood vessel walls and increase both skin and muscle blood flow as long as cardiac output is maintained. With obstructive arterial disease, however, vessels are sclerotic and unable to further dilate. As a result, healthy vessels dilate to a greater extent than diseased vessels, and blood flow is redistributed (shunted) away from areas that have the greatest need. BP and perfusion paradoxically drop even further in tissues affected by atherosclerosis, resulting in increased pain. If this process produces ischemia, it is known as the *steal phenomenon.* Thus, although nitrates are not contraindicated in patients like R.L, they may not be as helpful as their mechanism of action may suggest.

Numerous vasodilators (ie, prostaglandin E_1, prostacyclin, isoxsuprine, papaverine, ethaverine, cyclandelate, niacin derivatives, reserpine, guanethidine, methyldopa, tolazoline, nifedipine) have been used to treat IC. None, however, has convincingly or consistently improved exercise performance, despite earlier beliefs that they were effective.[104,105] Limited data suggest L-carnitine 1 g twice daily may have benefit in walking distance and initial claudication distance.[106] ACE inhibitors are the exception to this rule, as their beneficial effects are likely independent of their vasodilator properties. One small, controlled study demonstrated improvement in walking distance with verapamil, a CCB, compared with placebo in patients with IC.[107] Further studies with verapamil are needed before its use can be recommended.

Smoking cessation, an exercise program, and cilostazol are the interventions that should reduce R.L.'s symptoms of IC to the greatest degree. Verapamil is a moderate cytochrome P-450 3A4 inhibitor and would be expected to increase concentrations of

cilostazol. The magnitude of this interaction has not been characterized, nor has its impact on efficacy and bleeding events been assessed. Based on the necessity of cilostazol therapy in R.L., along with the poorly characterized benefits of verapamil in IC and the plethora of other antihypertensive and antianginal agents, avoidance of verapamil is prudent at this time. If additional BP or antianginal effects are needed, β-blockade or amlodipine can be initiated.

OTHER ANTITHROMBOTIC ALTERNATIVES

Case 10-1, Question 10: If R.L. experienced a cardiovascular event while on aspirin, what changes to his antithrombotic regiment should be made?

Although there are limited data regarding antithrombotic therapy in patients with PAD, vorapaxar has been approved with potential to provide a benefit in reducing cardiovascular events. Vorapaxar is a platelet protease-activated receptor (PAR)-1 antagonist, which inhibits thrombin-mediated platelet and recently received FDA approval for reducing thrombotic cardiovascular events in patients with PAD. The indication approval was based on a recent study, which enrolled 26,449 patients with stable atherosclerotic vascular disease who were already receiving dual antiplatelet therapy, of which 14% had PAD.[108] The results showed that treatment with vorapaxar reduced the composite primary end point of cardiovascular death, MI stroke, although only the incidence of MI was reduced significantly. Importantly, major bleeding was increased significantly in the vorapaxar group; thus, the true benefit of the addition of vorapaxar in these patients is unclear at this time.

Dual pathway inhibition with low-dose oral factor Xa inhibitor rivaroxaban plus low-dose aspirin was recently evaluated in two studies that demonstrate its benefit in patients with PAD. The first study evaluated 27,295 patients with stable ASCVD, of which 27% had PAD. Patients were randomized to one of three groups: rivaroxaban 2.5 mg twice daily plus aspirin 100 mg daily, rivaroxaban

5 mg twice daily, or aspirin 100 mg daily.[109] The trial was stopped early because of the significant outcome benefit in the patients who received the combination of rivaroxaban 2.5 mg twice daily plus aspirin. This combination reduced the primary composite end point of cardiovascular death, MI, and stroke, along with death from any cause, and the results were consistent across all ASCVD groups. Guidelines have now included this combination as an option to reduce ASCVD risk.[24]

CASE 10-1, QUESTION 11: Three years have passed, and R.L. stopped smoking 6 months ago. His current medications include isosorbide mononitrate 60 mg daily, aspirin 81 mg daily, and ramipril 10 mg daily; carvedilol 6.25 mg twice a day; NPH insulin 55 units in the morning and 40 units in the evening; and atorvastatin 80 mg daily. His symptoms of IC have remained fairly stable until the recent development of a nonhealing ulcer on his toe. What options are there for R.L. if nonpharmacologic and pharmacologic interventions are not sufficient?

Surgical intervention eventually may be necessary for persistent and complicated disease. Because success rates for preventing amputation and postsurgical complications vary from institution to institution, surgery should be considered only for severely ischemic limbs and should be performed in a hospital with a good record of success.[110] Arterial bypass grafting and percutaneous transluminal angioplasty of the femoral or iliac arteries, similar to cardiac revascularization, are two procedures that can be performed. Angioplasty is beneficial in patients with localized disease, especially in the iliac or superficial femoral arteries, and should be considered in patients who truly are incapacitated by their activity limitations.[111] Angioplasty with or without stent deployment, atherectomy, and the use of drug-eluting stents in the peripheral arteries are all options.[8] The more invasive reconstructive arterial (bypass) surgery can be used if diffuse lesions preclude the use of localized angioplasty. The true benefits and pitfalls of these skilled interventions remain unclear.[112]

Emergency surgical intervention may be required if acute, persistent ischemia develops. This is frequently because of

thrombosis associated with advanced atherosclerosis, although other causes, such as cardiac emboli, cannot be excluded.[103] Both surgical thrombectomy and localized thrombolytic administration[113] with tissue-plasminogen activator or urokinase have equal success in alleviating acute limb-threatening ischemia.[114,115] After surgical intervention, patients are advised to resume and remain on antiplatelet therapy indefinitely to reduce the risk of future events.

Dual pathway inhibition with low-dose rivaroxaban plus aspirin is a promising option for patients who require intervention. The Voyager study evaluated 6564 patients with PAD who had undergone lower extremity revascularization and were at high risk for major limb and cardiovascular events.[116] Compared to patients receiving aspirin alone, the combination of rivaroxaban 2.5 mg twice daily plus aspirin 100 mg daily significantly reduced the primary composite end point of acute limb ischemia, major amputation for vascular causes, MI, ischemic stroke, or death from cardiovascular causes.

RAYNAUD PHENOMENON

Raynaud phenomenon (RP) is a clinical syndrome caused by episodic vasospasm and ischemia of the extremities in response to cold, emotional, or physical stimuli.[117–122] Episodes include changes in color of the extremities from white, because of vasoconstriction, to blue, signaling tissue hypoxia, and then red when reperfusion occurs.[118] It is usually limited to the skin of the fingers, and less often the toes, but can also occur on the nose, cheeks, and ears.[119] Between attacks, the digits may appear cool and moist or normal. In most cases, the ischemia produced by the phenomenon does not have important consequences; however, in severe cases, atrophy of the skin, irregular nail growth, and wasting or ulceration of the tissue pads can occur.[119] Although both IC and RP are disorders of the peripheral arterial circulation, they differ significantly in that IC results primarily from atherosclerotic obstruction, whereas Raynaud disease is caused by vasospasm.

Diagnosis

This disorder can be separated into primary RP, indicating an idiopathic origin, and secondary RP, which consists of signs and symptoms of RP in the presence of an associated disease or condition, most commonly a connective tissue disorder, such as systemic sclerosis (formerly known as scleroderma), mixed connective tissue disease, rheumatoid arthritis, or systemic lupus erythematosus. Primary RP is more common (89% of patients) and is more likely to occur in younger patients (<30 years), generally presents with less severe symptoms, normal erythrocyte sedimentation rate, negative antinuclear antibodies, and no associated signs of underlying disease. Patients with secondary RP are more likely to have severe disease with painful symptoms, which can progress to ulceration or gangrene in extremities if untreated.[119] The diagnosis is generally a subjective one, consisting of clinical signs and symptoms, cold hands, feet, or both without normal recovery after a cold stimulus, emotional stress, or physical stress (such as vibrations) to the extremities.[121,122] In unaffected individuals, a cold provocation should result in some mottling and cyanotic changes in the hands, with recovery once the stimuli are removed. In patients with RP, however, the same cold provocation causes closure of the digital arteries, which produces a sharply demarcated pallor and cyanosis of the digits that persists despite removal of the stimulus.[121]

Epidemiology

In general, the prevalence of RP is about 3% to 5% across several ethnic groups[120]; however, it is higher in some geographically defined populations.[120] It is more common in females than males, is more frequent in non-Hispanic Whites, and has a higher prevalence in patients with family members who also experience RP. An onset in the teenage years suggests primary RP, whereas an onset after age 30 years suggests a secondary cause.[120] Secondary RP is usually associated with a connective tissue disorder, but several other

conditions may predispose individuals to its development. These include occupational-related exposures to vibratory machinery (eg, drills, chain saws) that cause neural damage,[120] vinyl chloride, or hand trauma.[122–124] Approximately 15% of patients diagnosed with primary RP will go on to develop a connective tissue disorder within 10 years.[125]

RP can also be associated with medications, including β-adrenergic blocking agents, ergots, cytotoxic drugs, chemotherapy, amphetamines and other sympathomimetics, and interferon, all of which can induce vasoconstriction.[126–128] Although avoidance of β-adrenergic blocking agents in patients with RP appears prudent, no discernible effect, as measured by skin temperature and blood flow, was found with the administration of both selective and nonselective β-blockers to patients with RP.[129] RP not associated with a connective tissue disorder is often transient and does not interfere with daily activities.[129] The effect of smoking on RP has yielded conflicting results. Overall, there appears to be a negligible effect of smoking on the prevalence of RP and the incidence of attacks, although there is some evidence that the severity of attacks may be decreased with smoking cessation.[130,131]

Pathophysiology

The pathophysiology involved in the exaggerated, abnormally long-lasting vasoconstriction in response to stimuli seen in RP is complex and still not completely understood. Control of blood vessel reactivity involves a balance of mediators released from circulating cells, the vascular endothelium, hormones, and neurotransmitters.[118,122] Cold-induced vasospastic attacks in patients with primary RP involve a heightened vasoconstriction of digital arteries that is mediated by a subset of peripheral α_2-adrenergic receptors.[118,122,132]

Vascular abnormalities noted in RP can include a deficiency of the vasodilator nitric oxide (NO), an increase in endothelial production of the potent vasoconstrictor endothelin-1, and increased activity of the renin–angiotensin system resulting in vasoconstriction induced by

angiotensin II.[122] In secondary RP, structural changes resulting from connective tissue disease may cause arterial damage that results in the α_2-adrenoreceptor aberrancy and endothelial injury that stimulates vasoconstriction, platelet activation, and impaired fibrinolysis.[118,122] It is also possible that serotonin receptors play a role in RP. Serotonin agonists have caused decreased finger blood flow, and, conversely, antagonists have increased digital blood flow.[133,134]

CASE 10-2

Question 1: L.G., a 39-year-old male, presents today with a 4-day history of left hand pain. He notes that the third digit of his left hand is "cold and somewhat blue," especially in the distal area. The other areas of his hand have recovered, but the distal portion of the digit remains cyanotic and numb. He has used acetaminophen and warm- water soaks without success. He is a construction worker who uses his hands "quite a bit" in his work. He has a history of gastroesophageal reflux and has no medication allergies. His social history is significant for smoking 1.5 packs of cigarettes a day for 19 years. On physical examination, his extremities reveal appropriate sensation of the forearm and hand. Some blue areas are noted on the distal portion on the third phalanx, with no other signs and symptoms. When L.G.'s opposite hand was placed in cold water, several white splotches appeared, and he experienced tingling in this hand as a result of the cold-water exposure. He is diagnosed as having RP.

Does L.G. present with primary or secondary RP?

Clinical Presentation

L.G. presents with what is most likely secondary RP owing to one of several potential underlying causes. His clinical presentation is classic for RP, with vasospasm, pallor, and a cyanotic overtone. The diagnosis is confirmed by the cold-water test, which indicates that the vasospastic attack is precipitated by cold exposure. He has a work history that may easily include hand trauma and the use of vibrating machinery, and his age also suggests secondary RP. Because of its association with connective tissue disorders, other

laboratory tests such as an antinuclear antibody and erythrocyte sedimentation rate should be checked.

Treatment

NONPHARMACOLOGIC MANAGEMENT

Case 10-2, Question 2: What conservative measures can be taken with L.G. to prevent or decrease the painful vasospasm of RP?

Most patients with either primary or secondary RP will respond to conservative management to reduce exposure to triggers such as cold and emotional stress.[119] L.G. should be instructed to protect his hands and fingers from exposure by using mittens and insulated wrappers when handling cold drinks and to protect other parts of his body from cold exposure. He should also try to minimize emotional stress and occupational exposure to vibrating machinery and avoid medications that can induce vasoconstriction, particularly sympathomimetics, clonidine, serotonin receptor agonists, and ergot preparations.[119,120] He should be encouraged to stop smoking, which may not affect occurrence of attacks but may decrease their severity and provide an overall positive health benefit.[130]

L.G. has new-onset and relatively mild RP. For others who have more severe symptoms and manifestations, especially patients with underlying connective tissue disorders, it is important to immediately and aggressively manage any ulcers that develop on the digits and to be extremely vigilant in detecting infected digits. Rarely, patients who have severe symptoms including ulceration or thrombosis may require surgical intervention such as peripheral sympathectomy, embolectomy, or ulcer debridement.[119,134,135]

CALCIUM CHANNEL BLOCKERS

Case 10-2, Question 3: Nifedipine extended-release 30 mg every day is ordered for L.G. What is the rationale for using a CCB in this case?

Medications can be used to treat primary and secondary RP if symptoms interfere with the patient's ability to work or perform daily activities or if digital lesions develop. Most proposed treatments for RP are variably effective, and they introduce the risk for significant side effects.[136,137] Drug therapy should always be in addition to nonpharmacologic measures.

Dihydropyridine CCBs decrease calcium ion influx and prevent vascular smooth muscle contraction, especially vascular responses evoked by cold exposure. Nifedipine, a potent peripheral vasodilator, has been studied the most and has become the drug of choice in patients with RP not controlled by conservative measures. In primary RP, 10 or more episodes per week are common. A meta-analysis showed a decrease of 2.8 to 5 attacks per week and a decrease in severity by 33%.[137] Patients with secondary RP experience a similar decrease in attack severity and also achieve a decrease in number of attacks with nifedipine therapy. Because their baseline number of attacks per week often exceeds 20, the relative benefit is not as great as with primary RP, averaging ~25% decrease in weekly episodes.[138] Although doses of 10 to 30 mg three times daily of immediate-release nifedipine are beneficial in studies,[137,138] most clinicians administer nifedipine as an extended-release formulation to increase convenience and decrease side effects such as dizziness, headache, facial flushing, and peripheral edema, which can occur in up to 50% of patients,[119,122,137] and this practice is supported by clinical studies.[139,140]

Although less thoroughly studied than nifedipine, other vasoselective CCBs, such as amlodipine, felodipine, isradipine, and nisoldipine, decrease the frequency and severity of ischemic attacks.[141–144] Patients who do not benefit from nifedipine likely will not benefit by switching to another CCB. Patients who cannot tolerate the side effects of nifedipine (eg, peripheral edema, headache) might benefit by switching to another CCB.

L.G. should be warned of the potential side effects with nifedipine therapy, especially dizziness associated with hypotension, and should return in 2 weeks for assessment. A 30-mg daily dose of extended-release nifedipine is a reasonable starting dose. He should

keep a diary documenting the number of attacks he experiences and the details surrounding each attack, such as time course and precipitating factors. In addition to the usual side effects mentioned above, L.G. should be aware that his symptoms of gastroesophageal reflux could worsen with nifedipine therapy, which can cause a decreased lower esophageal sphincter pressure. This side effect should be specifically assessed at his follow-up appointment.

OTHER THERAPEUTIC AGENTS

CASE 10-2, QUESTION 4: What other drugs may be tried if L.G. cannot tolerate the CCB?

Other than CCBs, no proven therapy for RP exists. Many agents, however, have been used based on limited data. The α_1-adrenergic antagonist prazosin, 1 mg three times a day, yielded moderate benefit in two-thirds of patients in two small studies.[145,146] Side effects of prazosin are significant at maximal doses and include dizziness, edema, fatigue, and orthostasis. The longer acting α_1-adrenergic antagonist terazosin was evaluated in one small study, and it improved symptomatology as well as objective measures of blood flow.[147] Insufficient data with this class of drugs exist to routinely recommend their initial use in patients with RP. Topical nitrates have been used clinically for several years and newer formulations have recently been studied, but data showing efficacy are limited.[119]

Several therapeutic approaches are being vigorously investigated and show promise as future therapies for RP. These include the intravenous prostaglandin analogs iloprost and alprostadil, which enhance nitric oxide–mediated vasodilation[148]; endothelin antagonists, such as bosentan[149]; and oral phosphodiesterase inhibitors[150–152] which also promote vasodilation. A meta-analysis of phosphodiesterase inhibitors for the treatment of secondary RP showed a modest decrease in frequency and duration of attacks, although further larger trials are needed.[152] Botulinum toxin-A has also been studied.[153] Because of side effects, cost, and

administration difficulties, these agents are primarily being studied in the most severe cases of secondary RP with digital ulcers or other systemic complications associated with connective tissue diseases. If benefit is proved, however, it will shed light on the pathogenesis of the disorder, and perhaps lead to therapies appropriate for the larger population with RP.

Statins may have promise in severe cases resulting in digital ulcers secondary to systemic sclerosis (SSc). Pleiotropic effects of atorvastatin 40 mg/day on endothelial function compared with placebo were investigated in 84 SSc patients who fulfilled the American College of Rheumatology criteria for classification of SSc with secondary RP despite ongoing vasodilator therapy. The study found a significant decrease in both new and the total number of digital ulcers in the atorvastatin group compared with placebo.[154]

The renin–angiotensin system mediators act as vasodilators and have been investigated in several small studies. ACE inhibitors and angiotensin receptor blockers, however, have yielded conflicting results with respect to beneficial effects in patients with RP.[155–158] Small beneficial effects have been realized, specifically with captopril 25 mg three times a day and losartan 12.5 to 25 mg/day; however, no benefit has been found with enalapril 20 mg once daily.[155] Fluoxetine, a selective serotonin reuptake inhibitor, was shown in one study to reduce the symptoms of RP.[159] It is hypothesized to exert its effect by depleting platelet serotonin, rendering the platelet unable to release a significant amount of the vasoconstrictive serotonin during activation and aggregation.

Alternative therapies, such as Ginkgo biloba and L-arginine, have also been studied in small trials with positive results; however, larger trials are needed to confirm the findings before these therapies can be recommended.[160–162]

All patients with RP should be counseled regarding cold avoidance and other protective measures. A CCB, extended-release nifedipine if tolerated, should be initiated if conservative measures are ineffective and titrated to the highest tolerated dose and symptom resolution. Combination therapies have not been investigated, but

another agent, such as an α_1-adrenergic antagonist, may be considered in addition to the CCB if symptom resolution is not satisfactory and side effects permit.

Thrombosis

Nancy L. Shapiro and Erika L. Hellenbart

CORE PRINCIPLES		CHAPTER CASES
1	Venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary embolism (PE), is caused by numerous additive risk factors, with diagnosis based on clinical findings and objective criteria.	**Case 11-1 (Questions 1–3)** **Case 11-5 (Question 1)**
2	VTE treatment includes parenteral anticoagulants (low-molecular-weight heparins or fondaparinux) bridging to a therapeutic international normalized ratio (INR) with warfarin, parenteral anticoagulants given before transitioning to dabigatran or edoxaban, or as monotherapy with rivaroxaban or apixaban.	**Case 11-1 (Questions 4–6, 9)** **Case 11-5 (Questions 2, 3)**
3	Unfractionated heparin is monitored with	**Case 11-1 (Questions 7, 8, 10–12)**

	the activated partial thromboplastin time (aPTT) test; dosing adjustments are used to maintain the aPTT in therapeutic range, as well as monitoring for adverse effects, including thrombocytopenia and bleeding.	**Case 11-2 (Question 1)**
4	Outpatient treatment of VTE is preferred over hospitalization for patients with DVT and low-risk PE and home circumstances that are adequate.	**Case 11-3 (Questions 1, 2)**
5	Anticoagulation prophylaxis should be used in hospitalized patients at risk for VTE.	**Case 11-4 (Question 1)**
6	Warfarin therapy is dosed and monitored according to therapeutic response as measured by the INR. Monitoring for adverse effects including hemorrhage is also essential for all anticoagulants.	**Case 11-5 (Questions 4–6)** **Case 11-6 (Questions 5, 6)** **Case 11-7 (Question 1)**
7	Warfarin therapy is influenced by multiple factors, and patients on warfarin require extensive and ongoing education to maintain safe and effective anticoagulation.	**Case 11-6 (Questions 1–4)** **Case 11-8 (Question 1)** **Case 11-13 (Question 1)** **Case 11-14 (Questions 1, 2)**
8	Warfarin and the direct oral anticoagulants (DOACs) are used for stroke prevention in nonvalvular atrial fibrillation. Warfarin is the only long-term oral option for stroke prevention or	**Case 11-9 (Questions 1–3)** **Case 11-10 (Question 1)** **Case 11-11 (Question 1)**

	thrombosis prevention in patients with mechanical heart valve replacement.	
9	Pharmacists can play an important role in the management of anticoagulant therapy for invasive procedures.	**Cases 11-12 (Question 1)**
10	Although the DOACs do not need monitoring to measure their efficacy, monitoring of baseline renal function and complete blood cell counts are necessary to ensure appropriateness of dosing and to minimize risk of anticoagulation-related bleeding complications.	**Case 11-3 (Question 1)** **Case 11-5 (Questions 2, 6)**

INTRODUCTION

Thrombosis is the process involved in the formation of a fibrin blood clot. Platelets and a series of coagulant proteins (clotting factors) contribute to clot formation. An embolus is a small part of a clot that breaks off and is carried by blood flow to another part of the vascular system. Damage is caused when the embolus becomes trapped in a small vessel, causing occlusion and leading to ischemia or infarction of the surrounding tissue. Normal clot formation maintains the integrity of the vasculature in response to injury, but pathologic clotting can occur in many clinical settings. Abnormal thrombotic events include venous thromboembolism (VTE; deep vein thrombosis [DVT] and its primary complication, pulmonary embolism [PE]), as well as stroke and other systemic manifestations of embolization of clots that form within the heart. Anticoagulant drug therapy is aimed at preventing pathologic clot formation in patients at risk and at preventing clot extension and/or embolization in patients who have experienced thrombosis. This chapter emphasizes arterial

and venous thromboembolic disease and the use of the parenteral anticoagulants (unfractionated heparin [UFH], low-molecular-weight heparins [LMWHs], indirect factor Xa inhibitors, and injectable direct thrombin inhibitors) and oral agents (vitamin K antagonists [VKAs], direct oral anticoagulants [DOACs], which include the oral direct thrombin inhibitors, and the oral direct factor Xa inhibitors). Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; Chapter 13, Acute Coronary Syndrome; and Chapter 61, Acute Ischemic and Hemorrhagic Stroke, provide more in-depth discussions of thrombolytic agents and antiplatelet therapy.

Etiology of Thromboembolism

Three primary factors influence the formation of pathologic clots and are described in a model referred to as the *Virchow triad* (**Fig. 11-1**).[1] Abnormalities of blood flow that cause venous stasis can result in DVT, which can progress to PE if embolization occurs. Intracardiac stasis of blood can also result in clot formation within the heart chambers, and embolization of intracardiac thrombi may lead to stroke or other systemic manifestations. Abnormalities of blood vessel walls, such as those that occur in injury or trauma to the vasculature, are a second source of thrombus formation. The presence of foreign material within the vasculature, including artificial heart valves and central venous catheters, is also thrombogenic and, as with vascular injury, represents the presence of an abnormal surface in contact with blood. Finally, hypercoagulability resulting from alterations in the availability or the integrity of blood clotting components or naturally occurring anticoagulants also represents a significant risk factor for thromboembolic disease.[2]

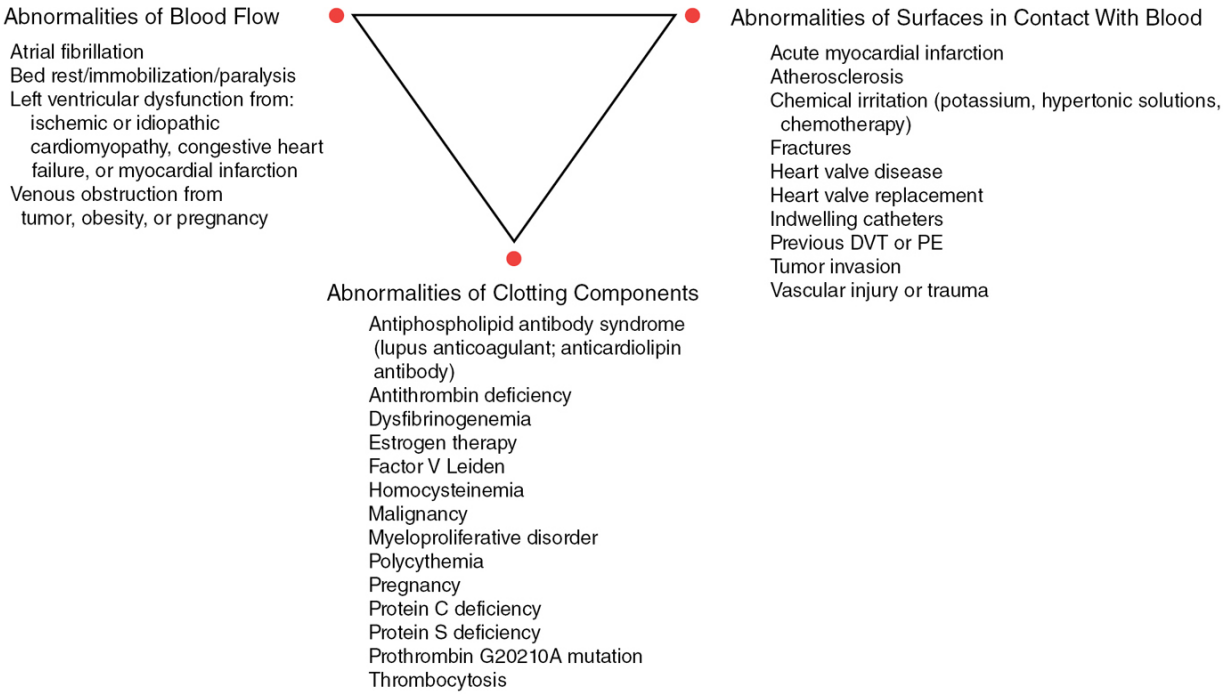

Figure 11-1 Risk factors for thromboembolism. DVT, deep vein thrombosis; PE, pulmonary embolism.

Clot Formation

The intact endothelial lining of blood vessels normally repels platelets and inhibits clot formation through secretion of numerous inhibitory substances. Damage to the endothelium leads to exposure of circulating blood to subendothelial substances, and this results in the formation of a fibrin clot.[2]

PLATELET ADHESION, ACTIVATION, AND AGGREGATION

Endothelial damage leads to exposure of blood to subendothelial collagen and phospholipids, resulting in platelet adhesion to the surface. Von Willebrand factor serves as the binding ligand for platelet adhesion, via the glycoprotein (GP) I receptor on the platelet surface. Adhered platelets become activated and release numerous compounds, including adenosine diphosphate and thromboxane A2, which stimulate platelet aggregation. Fibrinogen serves as the

binding ligand for platelet aggregation, via the GPIIb/IIIa receptor on the platelet surface.[2]

CLOTTING CASCADE

Transformation of the relatively unstable platelet plug (ie, the aggregated platelets) to a stable fibrin clot occurs as a result of an imbalance between other procoagulant and anticoagulant factors. In addition to stimulating the platelet response, endothelial damage results in activation of the extrinsic pathway of the clotting cascade by the release of thromboplastin (tissue factor) (**Fig. 11-2**). Tissue factor converts factor VII to factor VIIa, which mediates the activation of factor X. The intrinsic pathway of the clotting cascade is activated by exposure of factor XII to subendothelial components exposed during vessel injury. The intrinsic pathway mediates factor X activation via a chain of events initiated by factor XI. The distinction between these pathways is primarily an in vitro phenomenon; in vivo, the two pathways are activated simultaneously.

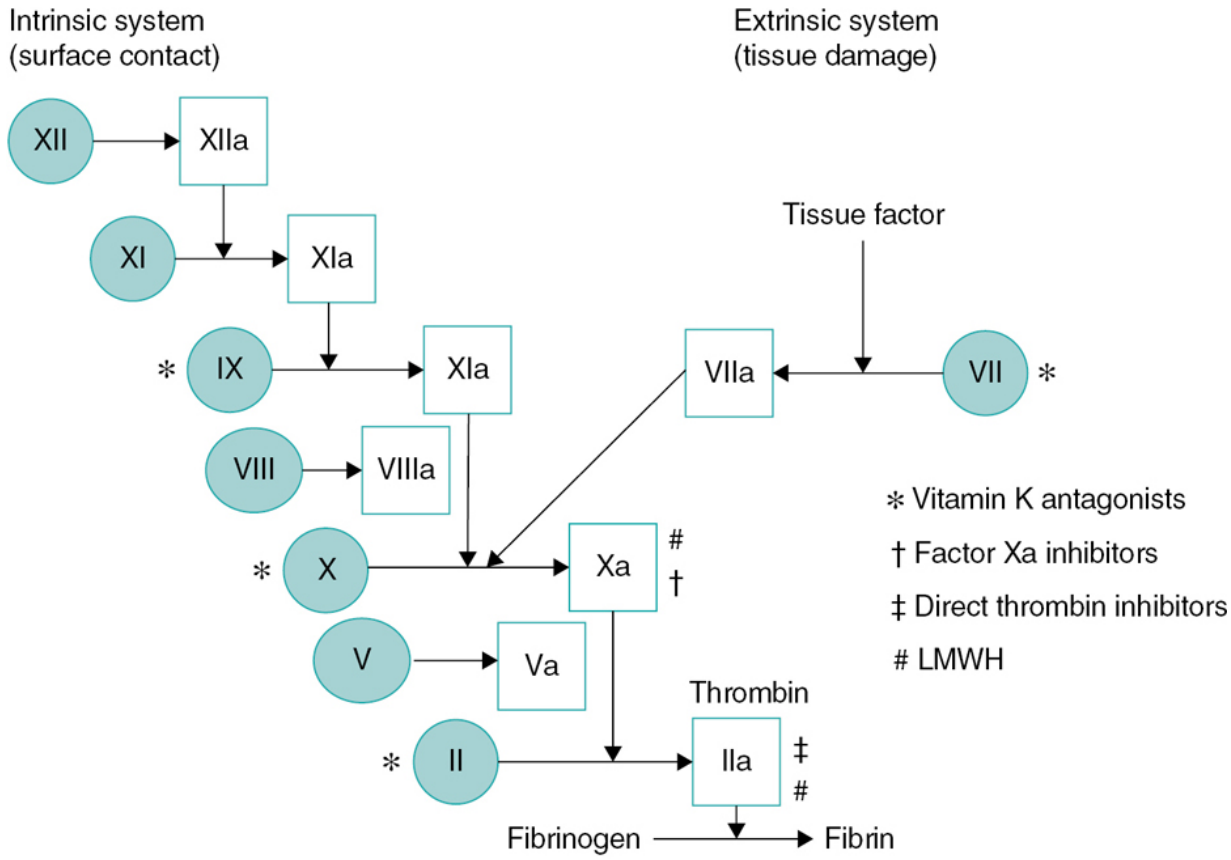

Figure 11-2 Simplified clotting cascade and respective anticoagulant targets. LMWH, low-molecular-weight heparin.

Once stimulated, both the extrinsic and intrinsic pathways activate the common pathway of the clotting cascade via factor X. Activated forms of factors V and VIII serve independently to accelerate this process. The final steps include conversion of factor II (prothrombin) to factor IIa (thrombin), with eventual formation of a stable fibrin clot.

Naturally occurring inhibitors of clotting factors play a role in localizing fibrin formation to the sites of injury and in maintaining the fluidity of circulating blood. **Table 11-1** outlines these clotting inhibitors and their primary actions. In addition, the fibrinolytic system is involved in degradation of fibrin clots. The actions of both clotting inhibitors and the fibrinolytic system prevent excessive coagulation. Thus, the process of clot formation is dynamic and involves various factors that can stimulate, inhibit, and dissolve a fibrin clot.

Table 11-1
Inhibitors of Clotting Mechanisms

Inhibitor	Target
Antithrombin	Inhibits factors IIa, IXa, and Xa
Protein S	Cofactor for activation of protein C
Protein C	Inactivates factors Va and VIIIa
Tissue factor pathway inhibitor	Inhibits activity of factor VIIa
Plasminogen	Converted to plasmin via tissue plasminogen activator
Plasmin	Lyses fibrin into fibrin degradation products

PATHOLOGIC THROMBI

Pathologic thrombi are sometimes classified according to location and composition. Arterial thrombi are composed primarily of platelets, although they also contain fibrin and occasional leukocytes. Arterial thrombi generally occur in areas of rapid blood flow (ie, arteries) and are typically initiated by spontaneous or

mechanical rupture of atherosclerotic plaques followed by aggregation of platelets (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; and Chapter 13, Acute Coronary Syndrome). Venous thrombi are found primarily in the venous circulation and are composed almost entirely of fibrin and erythrocytes. Venous thrombi have a small platelet head and generally form in response to either venous stasis or vascular injury after surgery or trauma. The areas of stasis prevent dilution of activated coagulation factors by normal blood flow.

The selection of an antithrombotic agent is influenced by the type of thrombus to be treated. The anticoagulant heparin, LMWHs, indirect and direct factor Xa inhibitors, direct thrombin inhibitors, and warfarin are used in the treatment and prevention of both arterial and venous thrombi. Drugs that alter platelet function (eg, aspirin, clopidogrel), alone and/or in combination with anticoagulants, are primarily used in the prevention of arterial thrombi. Fibrinolytic agents are used for rapid dissolution of thromboemboli, most notably during myocardial infarction (MI).

Pharmacology of Antithrombotic Agents

HEPARIN

Heparin is a rapid-acting anticoagulant that is administered parenterally. Standard heparin (UFH) is a heterogeneous mixture of glycosaminoglycans of varying molecular weights obtained from bovine lung or porcine intestinal mucosa (**Table 11-2**). The action of heparin is facilitated by its binding to the naturally circulating anticoagulant antithrombin (AT), a serine protease also referred to as heparin cofactor. Binding of heparin to AT accelerates the anticoagulant effect of AT. The heparin–AT complex attaches to and irreversibly inactivates factor IIa (thrombin) and factor Xa as well as activated factors IX, XI, and XII.[3] Approximately one-third of the molecules present in UFH bind to AT and provide the anticoagulant properties of heparin. The remaining two-thirds of the heparin molecules bind to plasma proteins and to endothelial cells. In

addition to its anticoagulant effects, heparin inhibits platelet function and increases vascular permeability; these properties contribute to the hemorrhagic effects of heparin.

Table 11-2

Comparison of Unfractionated Heparin, Low-Molecular-Weight Heparins, and Fondaparinux

Property	UFH	LMWH	Fondaparinux
Molecular weight range[a]	3000–30,000	1000–10,000	1728
Average molecular weight[a]	12,000–15,000	4000–5000	1728
Anti-Xa: anti-IIa activity	1:1	2:1–4:1	>100:1
aPTT monitoring required	Yes	No	No
Inactivation by platelet factor 4	Yes	No	No
Capable of inactivation of platelet-bound factor Xa	No	Yes	Yes
Inhibition of platelet function	++++	++	No
Increases vascular permeability	Yes	No	No
Protein binding	++++	+	No
Endothelial cell binding	+++	+	No
Dose-dependent clearance	Yes	No	No
Primary route of elimination	Saturable binding processes Renal	Renal	Renal
Elimination half-life	30–150 minutes	2–6 hours	17 hours

LMWH, low-molecular-weight heparin; UFH, unfractionated heparin +, low; ++, moderate; +++, high; ++++, very high.

In cases of acute DVT or PE, the clotting cascade has been activated, generating abnormal quantities of thrombin and fibrin. In these situations, thrombin must be inactivated directly, a process that may require relatively large doses of heparin. However, when the clotting cascade is in a normal balance, it is possible to indirectly inactivate thrombin with smaller heparin doses by complexing factor Xa. Because of the amplification effect of the clotting cascade, inactivation of relatively small amounts of factor Xa indirectly prevents the production of large quantities of thrombin. This

phenomenon is the basis for low-dose heparin prophylaxis after surgery or in cases of prolonged bed rest or immobilization.

Heparin may be administered intravenously (IV) by continuous infusion, or subcutaneously (SC), although its bioavailability is significantly reduced by SC administration. Intramuscular administration of heparin (as well as intramuscular administration of other drugs in patients who are anticoagulated) should be avoided because of the potential for hematoma formation.

After IV administration, the anticoagulant effect of heparin is noted immediately. During active thromboembolism, the high concentration of clotting factors necessitates a higher concentration of heparin to neutralize them. This increased dosing requirement may also be related to continuing thrombin formation on the surface of the thrombus. Once endothelialization (localization and incorporation of the clot into the vascular endothelium) of the clot begins and the concentration of clotting factors decreases, dosing requirements typically decrease. Considerable variability in dosing requirements among patients necessitates routine therapeutic monitoring to maintain an appropriate intensity of anticoagulation with heparin. The primary laboratory test for monitoring therapeutic heparinization is the activated partial thromboplastin time (aPTT; see section on Tests Used to Monitor Antithrombotic Therapy).

The plasma half-life of heparin varies from 30 to 150 minutes, but the half-life increases with increasing doses. Heparin is cleared by extensive binding to plasma proteins and endothelial cells, saturable processes that explain both its nonlinear kinetics and the variability in dosing requirements among patients. Additional clearance occurs by transfer to the reticuloendothelial system, with ultimate elimination controlled by the kidneys.

LOW-MOLECULAR-WEIGHT HEPARINS

Using chemical or enzymatic depolymerization techniques, UFH can be separated into fragments based on molecular weight.[3] Several LMWH molecules have been isolated and commercially marketed as anticoagulants. The LMWH products available in the United States

are dalteparin and enoxaparin, and tinzaparin is available in the non-U.S. market (**Table 11-3**). These products have replaced the use of UFH in many clinical situations. These compounds differ substantially from UFH with respect to molecular weight, antithrombotic and pharmacokinetic properties, adverse effect profiles, and monitoring requirements (see Table 11-2).

Table 11-3
Low-Molecular-Weight Heparin Products

Generic Name	Brand Name	Average Molecular Weight (Range)[a]	Anti-Xa: Anti-IIa Activity
Dalteparin	Fragmin®	5000 (2000–9000)	2.0:1
Enoxaparin	Lovenox®	4500 (3000–8000)	2.7:1
Tinzaparin[b]	Innohep®	4500 (3000–6000)	1.9:1

[a]Measured in Daltons.

[b]Not available in the United States.

To inactivate factor Xa, only the AT component of the heparin–AT complex is required to bind to factor Xa. Both the longer, high-molecular-weight fragments of UFH and the shorter, low-molecular-weight fragments of LMWHs are capable of inactivating factor Xa. However, to inactivate factor IIa (thrombin), both the heparin component and the AT component of the heparin–AT complex are required to bind to factor IIa. This binding requires heparin molecules of at least 18 saccharide units in length, which are less prevalent in LMWHs. Therefore, the anti-Xa properties of LMWHs are more significant than are their anti-IIa properties. The resultant antithrombotic effect does not prolong the aPTT, meaning that these compounds do not require laboratory monitoring in most clinical circumstances to ensure a therapeutic effect.

Additional advantages of LMWHs over UFH are explained by their reduced binding affinity for plasma proteins and endothelial cells. These compounds display improved bioavailability after SC injection, a predictable dose response, and a longer pharmacodynamic effect compared with UFH. In general, these compounds are administered SC every 12 to 24 hours at fixed doses. The LMWH products have been studied in the prevention and treatment of thromboembolic disease. They differ significantly in their molecular weight

distributions, methods of preparation, and the ratio of anti-Xa: anti-IIa activities, as well as in their pharmacokinetic and pharmacodynamic characteristics (see Table 11-2).

FACTOR XA INHIBITORS

Fondaparinux is a selective indirect factor Xa inhibitor that is indicated for the prevention of venous thrombosis associated with orthopedic and abdominal surgeries, and for the treatment of DVT and PE.[3,4] It is a synthetic derivative of the five-residue saccharide sequence found in both UFH and LMWH that binds to AT to inactivate factor Xa with no direct impact on factor IIa. This agent has a long elimination half-life, allowing for once-daily SC administration at a fixed dose without the need for routine coagulation monitoring (see Table 11-2).

Direct factor Xa inhibitors include the oral agents apixaban, edoxaban, rivaroxaban, and betrixaban. The first three are approved by the U.S. Food and Drug Administration (FDA) for stroke prevention in nonvalvular atrial fibrillation, and prevention and treatment of VTE, with other indications described (**Table 11-4**). Betrixaban is indicated for prophylaxis of VTE in adult patients hospitalized for an acute medical illness but is no longer marketed in the United States. These agents have a short onset of action and elimination half-life, are given at fixed doses, and do not require routine monitoring or dose adjustments, which offer significant benefits to warfarin therapy as chronic therapy (**Table 11-5**). Each has varying dependence on renal function for elimination, but all require dose adjustments in patients with renal dysfunction. However, low body weight or advanced age necessitates a dose reduction for apixaban (Table 11-4). All are substrates of P-glycoprotein (P-gp); thus, concomitant use of inducers and inhibitors of P-gp can, respectively, decrease and increase its serum concentration. In addition, rivaroxaban and apixaban are both substrates of cytochrome P450 enzyme 3A4 (CYP3A4) and require dose adjustments when used concomitantly with certain CYP3A4 inhibitors or inducers (**Tables 11-4** and **11-6**).

Table 11-4
Indications and Doses for DOACs

DOAC	Indication	Dose
Dabigatran	Stroke prevention in NVAF	CrCl >30 mL/minute: 150 mg bid CrCl 30–50 mL/minute: decrease to 75 mg bid or avoid if on P-gp inhibitor CrCl 15–30 mL/minute: 75 mg bid or avoid if on P-gp inhibitor CrCl <15 mL/minute or on dialysis: contraindicated
	Treatment of DVT and PE	CrCl >30 mL/minute: LMWH or UFH × 5–10 days, then dabigatran 150 mg bid CrCl <50 mL/minute and on P-gp inhibitor: avoid coadministration CrCl ≤30 mL/minute or on dialysis: dosing recommendations cannot be provided.
	Prevention of recurrent DVT and PE	(CrCL >30 mL/minute): 150 mg bid
	Prevention of VTE after total hip replacement	(CrCl >30 mL/minute): 110 mg × 1 day, then 220 mg daily
Rivaroxaban	Stroke prevention in NVAF	Dosed with evening meal: CrCl >50 mL/minute: 20 mg daily CrCl 15–50 mL/minute: 15 mg daily CrCl <15 mL/minute: avoid
	Treatment of DVT and PE	CrCl ≥30 mL/minute: 15 mg bid × 21 days, then 20 mg daily CrCl <30 mL/minute: avoid
	Prevention of recurrent DVT and PE	10 mg daily
	Prevention of VTE after TKR and THR	10 mg daily for 12 days (TKR) or 35 days (THR)
	Prevention of VTE in hospitalized acutely ill medical patients	10 mg daily in hospital and after hospital discharge for total duration of 31–39 days

DOAC	Indication	Dose
	Prevention of MACE in patients with chronic CAD or PAD	2.5 mg bid in combination with aspirin (75–100 mg) daily
Apixaban	Stroke prevention in NVAF	Most patients: 5 mg bid Any two of the following: 2.5 mg bid: SCr ≥1.5 mg/dL Age ≥80 years Weight ≤132.28 pounds (60 kg)
	Treatment of DVT and PE	10 mg bid × 7 days, then 5 mg bid No dose adjustment is recommended for renal function.[a] Strong dual inhibitors of CYP3A4 and P-gp: reduce dose by 50% or avoid coadministration. Dual P-gp inducers and strong CYP3A4 inducers: Avoid concomitant use.
	Prevention of recurrent DVT and PE	2.5 mg bid
	Prevention of VTE after TKR and THR	2.5 mg bid for 12 days (TKR) or 35 days (THR)
Edoxaban	Stroke prevention in NVAF	CrCl >95 mL/minute: Do not use. CrCl >50–95 mL/minute: 60 mg daily CrCl 15–50 mL/minute: 30 mg daily CrCl <15 mL/minute: Use is not recommended.
	Treatment of DVT and PE	CrCl >50 mL/minute: LMWH or UFH × 5–10 days, then edoxaban 60 mg daily CrCl 15–50 mL/minute: 30 mg daily CrCl <15 mL/minute: Use is not recommended. Patients ≤60 kg or on P-gp inhibitors: 30 mg daily
Betrixaban	Prevention of DVT and PE in adults hospitalized for acute medical illness	CrCl >30 mL/minute: 160 mg × 1 dose, then 80 mg daily for 35–42 days CrCl 15–30 mL/minute: 80 mg × 1 dose, then 40 mg daily × 35–42 days

bid, twice daily; CAD, coronary artery disease; CrCl, creatinine clearance; CYP, cytochrome P450; DVT, deep vein thrombosis; MACE, major cardiovascular events; NVAF, nonvalvular atrial fibrillation; PAD, peripheral artery disease; PE, pulmonary embolism; P-gp, P-glycoprotein; SCr, serum creatinine; THR, total hip replacement; TKR, total knee replacement; VTE, venous thromboembolism.

[a]Patients with creatinine clearance (CrCl) <25 mL/minute excluded from clinical trials for apixaban.

P-gp substrate	Yes	Yes	Yes	Yes	Yes
Hepatic impairment	Recommendations not available	Avoid in moderate or severe impairment or with any hepatic disease associated with coagulopathy.	Not recommended in severe impairment	Not recommended in moderate or severe impairment	Not recommended

CYP, cytochrome P450; DOACs, direct oral anticoagulants; P-gp, P-glycoprotein.

Table 11-6
Examples of Major DOAC Drug–Drug Interactions

DOAC	Drug Interaction	Recommendations
Dabigatran	P-gp inhibitors	Reduce dose or avoid depending on renal function.
	P-gp inducers	Avoid use.

Apixaban	Strong CYP3A4 inhibitor + P-gp inhibitor	Reduce dose or avoid use.
	Moderate CYP3A4 inhibitor + P-gp inhibitor	No dose adjustment required; use with caution. Avoid use in severe renal insufficiency.
	Strong CYP3A4 inducer + P-gp inducer	Avoid use.
Rivaroxaban	Strong CYP3A4 inhibitor + P-gp inhibitor	Avoid use.
	Moderate CYP3A4 inhibitor + P-gp inhibitor	No dose adjustment required; avoid use in severe renal insufficiency.
	Strong CYP3A4 inducer or P-gp inducer	Avoid use.
Edoxaban	P-gp inhibitors	AF: Do not reduce dose. VTE treatment: reduce dose.
	P-gp inducers	Avoid use with rifampin.

Refer to current product package inserts for further information as well as the U.S. Food and Drug Administration (FDA) website at https://www.fda.gov/drugs/drug-interactions-labeling/drug-development-and-drug-interactions-table-substrates-inhibitors-and-inducers.

Example drug interactions:

Strong CYP3A4 inhibitor + P-gp inhibitor: itraconazole, ketoconazole, ritonavir

Moderate CYP3A4 inhibitor + P-gp inhibitor: clarithromycin, diltiazem

Strong CYP3A4 inducer + P-gp inducer: carbamazepine, phenytoin, rifampin, St. John wort

Strong CYP3A4 inducers: carbamazepine, phenytoin, rifampin, St. John's wort

P-gp inhibitors: amiodarone, clarithromycin, cyclosporine, dronedarone, erythromycin, ketoconazole, nifedipine, ticagrelor, tacrolimus, verapamil

P-gp inducers: carbamazepine, phenytoin, rifampin, St. John's wort

AF, atrial fibrillation; CYP, cytochrome P450; DOAC, direct oral anticoagulant; P-gp, P-glycoprotein; VTE, venous thromboembolism.

DIRECT THROMBIN INHIBITORS

Argatroban and bivalirudin are injectable direct thrombin inhibitors that are used as alternative anticoagulants in patients with heparin-

induced thrombocytopenia (HIT; **Table 11-7**).[5] Direct thrombin inhibitors bind to specific sites on the thrombin molecule to inhibit its activity, without acting through a cofactor such as AT. These agents are administered by continuous infusion and require aPTT monitoring for appropriate dosing adjustments. Bivalirudin is also used in patients with acute coronary syndrome, including those undergoing percutaneous coronary intervention (see Chapter 13, Acute Coronary Syndrome).

Table 11-7
Pharmacologic and Clinical Properties of Injectable Direct Thrombin Inhibitors

	Bivalirudin	**Argatroban**
Route of administration	IV	IV
FDA-approved indication	Patients with UA undergoing PTCA; PCI with provisional use of GPI; patients with or at risk for HIT/HITTS undergoing PCI	Treatment of thrombosis in patients with HIT; patients at risk for HIT undergoing PCI
Binding to thrombin	Partially reversible at catalytic site and exosite-1	Reversible at catalytic site
Half-life in healthy subjects	25 minutes	40–50 minutes
Monitoring	aPTT/ACT SCr/CrCl	aPTT/ACT Liver function
Clearance	Enzymatic (80%) Renal (20%)	Hepatic
Antibody development	May cross-react with antihirudin antibodies	No
Effect on INR	Slight increase	Increase
Initial dose for HIT	No bolus Infusion: 0.15 mg/kg/hour	No bolus Infusion: 2 µg/kg/minute[a] In critically ill patients: Consider lower infusion rate of 0.2–1 µg/kg/minute

Initial dose for PCI	Bolus: 0.75 mg/kg Infusion: 1.75 mg/kg/hour	Bolus: 350 μg/kg Infusion: 25 μg/kg/minute

ACT, activated clotting time; aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; FDA, U.S. Food and Drug Administration; GPI, glycoprotein IIb-IIIa inhibitor; HIT, heparin-induced thrombocytopenia; HITTS, heparin-induced thrombocytopenia and thrombosis syndrome; IV, intravenous; PCI, percutaneous coronary intervention; PTCA, percutaneous transluminal coronary angioplasty; SCr, serum creatinine; UA, unstable angina.

[a]In some cases, an initial infusion rate of <1.5 μg/kg/minute may be more appropriate.

Dabigatran is an oral direct thrombin inhibitor, approved for stroke prevention in patients with nonvalvular atrial fibrillation, the treatment of VTE, and the extended treatment of VTE.[6] Similar to the direct factor Xa inhibitors, dabigatran is given at a fixed dose without the need for routine coagulation monitoring or dosing adjustments.[6] It has a short onset of action and elimination half-life in patients with normal renal function, which reduces the need for bridging therapy with LMWH as is necessary during warfarin initiation or interruption (see Table 11-4). Owing to its low bioavailability, dabigatran is administered as a prodrug, dabigatran etexilate, in a capsule form that contains small micropellets that coat dabigatran with tartaric acid, creating an acidic microenvironment. It is then rapidly converted to the active compound by hydrolysis and then eliminated renally. When it is not supplied or stored in the original packaging, capsule exposure to humidity leads to degradation of dabigatran etexilate via hydrolysis. The shelf life of dabigatran is 4 months if stored and sealed in the original bottle and desiccant-containing cap. Blister packs are available for unit-dose administration. Elimination of dabigatran is highly dependent on renal function, so dosing adjustments are required in these patients (see Table 11-5). Dabigatran is a substrate of P-gp; thus, concomitant use of inducers and inhibitors of P-gp can, respectively, decrease and increase its serum concentrations. However, because dabigatran is not metabolized by cytochrome P450 (CYP) enzymes, it is not susceptible to CYP-mediated drug interactions (see Table 11-6). Collectively, the oral direct thrombin inhibitors and the oral direct

factor Xa inhibitors are referred to as *direct oral anticoagulants (DOACs)*. The DOACs are the preferred anticoagulant agents for most patient care scenarios and provide opportunities for pharmacist involvement in drug selection, patient education, and long-term therapeutic management.

WARFARIN

Warfarin is an oral anticoagulant with a delayed onset of effect that acts as a VKA. Vitamin K is essential for the conversion (carboxylation) of precursors to clotting factors II, VII, IX, and X into inactive clotting factors and for the synthesis of the naturally occurring anticoagulants, protein C and protein S. During factor conversion, vitamin K is oxidized to inactive vitamin K epoxide (**Fig. 11-3**). In the nonanticoagulated patient, vitamin K epoxide is in reversible equilibrium with vitamin K, but this equilibrium is disrupted in patients taking oral VKAs. Warfarin interferes with the hepatic recycling of vitamin K by inhibiting vitamin K epoxide reductase (VKOR), the enzyme that converts vitamin K epoxide to vitamin K.[6] The accumulation of vitamin K epoxide reduces the effective concentration of vitamin K and reduces the synthesis of coagulation factors. Concentrations of clotting factors II, VII, IX, and X are diminished gradually at rates commensurate with their elimination half-lives (**Table 11-8**). Thus, the onset of the anticoagulant effect of warfarin is delayed. It takes ~5 to 7 days to reach a steady state of anticoagulation after warfarin therapy is initiated or after dosing changes. Protein C and its cofactor protein S are also vitamin K dependent, and these proteins are depleted by warfarin at rates dependent on their elimination half-lives.

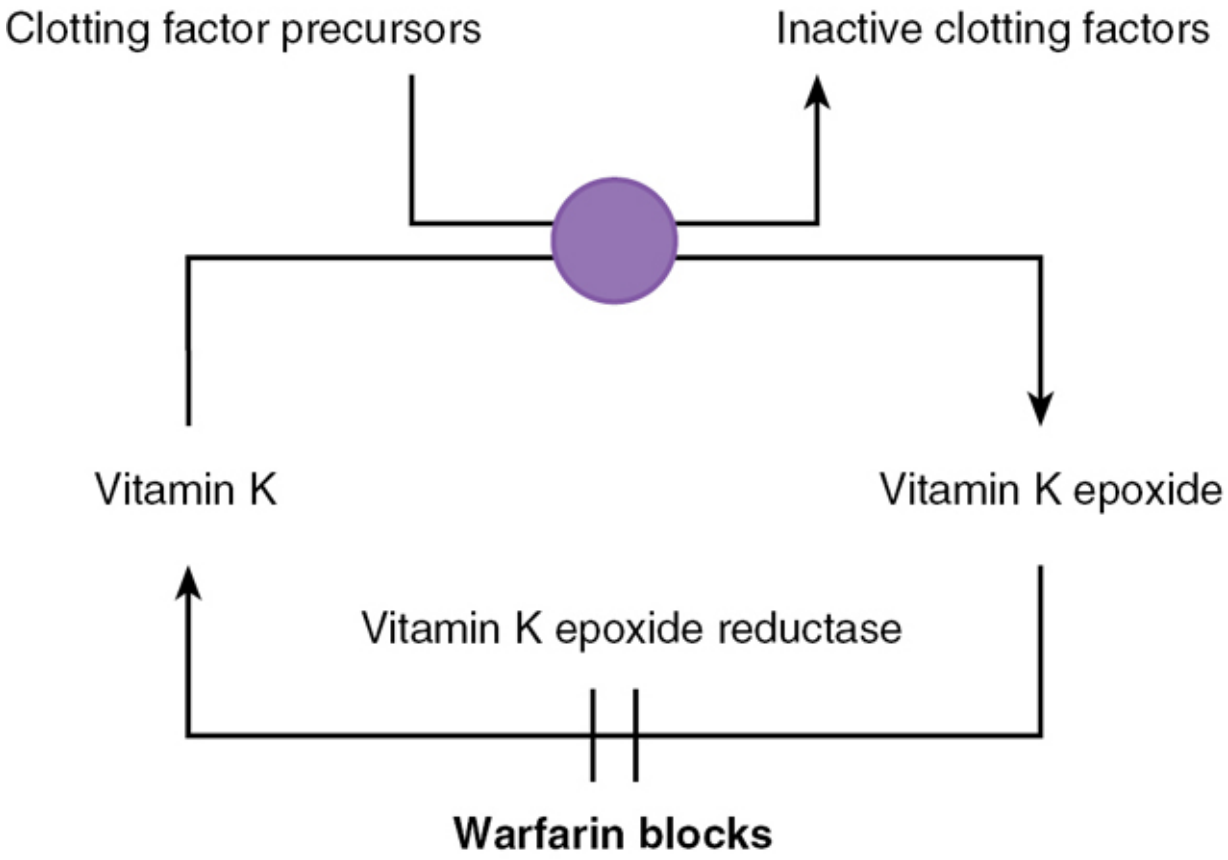

Figure 11-3 Mechanism of action of warfarin.

Table 11-8
Elimination Half-Lives of Vitamin K–Dependent Clotting Factors

Clotting Factor	Half-Life (hours)
II	42–72
VII	4–6
IX	21–30
X	27–48
Protein C	9
Protein S	60

Warfarin is rapidly and completely absorbed in the upper gastrointestinal (GI) tract by passive diffusion, with nearly 100% bioavailability. Peak absorption of warfarin occurs in 60 to 120 minutes. It is ~99% bound to serum albumin. The volume of

distribution for warfarin is 12.5% of body weight. This small volume of distribution is consistent with the extensive binding of warfarin to albumin. The primary laboratory test for monitoring warfarin therapy is the prothrombin time (PT). No correlation appears to exist between PT and the dose of warfarin, the total warfarin concentration, or the free warfarin concentration for any population of treated patients, although in individual patients, an increasing dose of warfarin will increase the serum concentration (free and total) and the PT.

Warfarin is administered orally as a racemic mixture containing equal parts of the enantiomers R(+)-warfarin and S(−)-warfarin. The S(−)-isomer is 2.7 to 3.8 times more potent as an anticoagulant than the R(+)-isomer, has a longer elimination half-life, and is primarily metabolized by CYP2C9. Comparatively, R(+)-warfarin is metabolized primarily by CYP1A2 and CYP3A4. Many drugs interact with warfarin by stereoselectively inhibiting the metabolism of the R(+)-isomer or the S(−)-isomer (see section on Drug Interactions).

Genetic expression of CYP2C9 influences the rate of metabolism of warfarin and thus impacts dosing requirements to meet a particular therapeutic end point.[7] Variability in genetic expression of VKORC1 (the complex 1 subunit on the gene that codes for vitamin K epoxide reductase) also influences dosing requirements in patients taking warfarin. Genetic testing for CYP2C9 genotype and VKORC1 haplotype can be incorporated with clinical and demographic information to predict warfarin dose requirements in individual patients, using dosing algorithms that have been developed and investigated. A practical example is available online at www.warfarindosing.org. Routine pharmacogenomic testing of warfarin is not currently endorsed at this time.

Tests Used to Monitor Antithrombotic Therapy

Before the initiation of any antithrombotic therapy, an assessment of baseline hemostatic status is necessary. The clinician should obtain a baseline platelet count and hemoglobin (Hgb) and/or hematocrit

(Hct), as well as evaluate the baseline integrity of the extrinsic and intrinsic coagulation pathways with PT and aPTT, the tests used to monitor warfarin and heparin, respectively. The DOACs do not require routine monitoring of laboratory tests to monitor their efficacy; however, baseline creatinine clearance (CrCl) and liver function tests (LFTs) are also needed with these agents.

PROTHROMBIN TIME/INTERNATIONAL NORMALIZED RATIO

The PT is prolonged by deficiencies of clotting factors II, V, VII, and X, as well as by low levels of fibrinogen and very high levels of heparin. It reflects alterations in the extrinsic and common pathways of the clotting cascade, but not in the intrinsic system.[8] The PT is measured by adding calcium and tissue thromboplastin to a sample of plasma from which platelets have been removed by centrifugation. The time to clot formation is detected by automated instruments using light scattering techniques that measure optical density. The mean normal PT, obtained by averaging a number of PT results from nonanticoagulated subjects, is ~12 seconds for most reagents.

The thromboplastins used in PT monitoring are extracted from various tissue sources by a number of techniques and prepared for commercial use as reagents. Unfortunately, thromboplastins are not standardized among manufacturers or among batches of reagent produced by the same manufacturer, leading to significant variability in PT results for anticoagulated patients. To standardize PT results, the World Health Organization developed a system by which all commercially available thromboplastins are compared with an international reference thromboplastin and then assigned an international sensitivity index (ISI). This value is used to mathematically convert PT to the international normalized ratio (INR) by exponentially multiplying the PT ratio to the power of the ISI of the thromboplastin being used in the laboratory to measure the test:

$$\mathrm{INR} = (\mathrm{PT\ patient} / \mathrm{PT\ mean\ normal})^{\mathrm{ISI}} \qquad \textbf{(Eq. 11-1)}$$

The ISI of the international reference thromboplastin is 1.0.

The INR is the internationally recognized standard for monitoring warfarin therapy.[6] Current recommendations for intensity of oral anticoagulation therapy for accepted clinical indications are summarized in **Table 11-9**. Regular intensity therapy is defined as dosing warfarin to reach a goal INR of 2.5 (range, 2.0–3.0) and is appropriate for most settings that require the prevention and/or treatment of thromboembolic disease. High-intensity therapy is used in mechanical valve replacement and certain situations of thromboembolic recurrence, despite adequate anticoagulation, and is defined as dosing warfarin to reach a goal INR of 3.0 (range, 2.5–3.5).

Table 11-9
Optimal Therapeutic Range and Duration of Anticoagulation

Indication	INR Goal	Minimum Duration
Prophylaxis of VTE (DVT, PE)	2–3	~1–4 weeks depending on patient status and risk factors
Treatment of first VTE with transient risk factors	2–3	3–6 months
First episode of unprovoked VTE	2–3	3–6 months Consider extended treatment if first episode of VTE is PE or proximal DVT with no bleeding risk factors.
Second episode of unprovoked VTE	2–3	Indefinitely
VTE and cancer	2–3	Indefinitely or until cancer resolved[a]
VTE prophylaxis after hip or knee arthroplasty, hip fracture surgery	2–3	Up to 35 days after surgery
AF (persistent or paroxysmal)/atrial flutter	2–3	Long term
Following placement of left atrial appendage occlusion device	2–3	45 days from procedure or until adequate seal of left atrial appendage is confirmed

Any mechanical valve in mitral position	2.5–3.5	Long term
Bileaflet mechanical valve or tilting disk valve in aortic position in sinus rhythm	2–3	Long term
Caged ball valve in aortic position	2.5–3.5	Long term
Mechanical On-X® valve in aortic position	2–3 1.5–2	3 months After initial 3 months of therapy
Mechanical aortic heart valves with additional risk factors (AF, previous VTE, LV dysfunction, hypercoagulable conditions)[b]	2.5–3.5	Long term
Bioprosthetic valve in aortic or mitral position[c]	2–3	3 to 6 months
Bioprosthetic valves with additional risk factors (AF, previous VTE, LV dysfunction, hypercoagulable conditions)[d]	2–3	Long term

AF, atrial fibrillation; DVT, deep vein thrombosis; INR, international normalized ratio; LV, left ventricle; PE, pulmonary embolism; VTE, venous thromboembolism.

[a]Low-molecular-weight heparin preferred for patients with venous thromboembolism (VTE) and cancer.

[b]Higher goal international normalized ratio (INR) recommended by the American Heart Association/American College of Cardiology (AHA/ACC). INR 2 to 3 recommended by the American College of Chest Physicians (ACCP).

[c]Long-term aspirin (75–100 mg) also recommended. Can be used alone in the absence of other indications for oral anticoagulation.

[d]Direct oral anticoagulant (DOAC) use may be considered after third postoperative month in patients with atrial fibrillation.

ACTIVATED PARTIAL THROMBOPLASTIN TIME

The aPTT reflects alterations in the intrinsic pathway of the clotting cascade and is used to monitor heparin and injectable direct thrombin inhibitors.[8,9] The test is performed by adding a surface-activating agent (kaolin or micronized silica), a partial thromboplastin reagent (phospholipid; platelet substitute), and calcium to the plasma sample. Mean normal values vary among reagents but typically fall between 24 and 36 seconds.

Similar to PT, the aPTT is a highly variable test based on differences among commercially available partial thromboplastin reagents. However, a system equivalent to the INR has not been developed for standardization of aPTT results. Heparinization to prolong the aPTT to 1.5 to 2.5 times the mean normal value historically was considered adequate to prevent propagation or extension of thrombus, but is no longer recommended because it is not appropriate for all reagents and testing systems. Instead, the aPTT should be calibrated for each reagent lot and coagulometer, and a reagent-specific therapeutic range in seconds that corresponds to therapeutic heparin levels of 0.3 to 0.7 IU/mL by factor Xa inhibition (anti-Xa activity) should be determined.[3,9,10] For direct thrombin inhibitors, the same aPTT goal range is used.

Hospital-based and independent clinical laboratories that offer aPTT monitoring will report the reagent-specific therapeutic range in seconds and adjust it as new reagents are purchased and used clinically.

ANTI-FACTOR XA ACTIVITY

Owing to the limitations of aPTT monitoring, researchers developed direct heparin concentration monitoring using heparin anti-Xa levels. Compared to the aPTT, the anti-Xa method is less impacted by biologic variables, although preanalytic and analytic variability remains.[11] The anti-Xa test costs more than the aPTT, but has some potential advantages, including fewer monitoring tests, fewer dose changes, and a shorter time to obtain therapeutic anticoagulation.[12] National guidelines for heparin monitoring recognize that there are

limitations to both approaches and do not recommend a preferred method.[10,13]

Although LMWHs do not require coagulation monitoring to ensure an appropriate antithrombotic effect or to adjust dosing, certain clinical situations may warrant assessment of the anti-factor Xa activity of LMWHs.[3] Because these agents are eliminated renally, patients with severe renal dysfunction may accumulate LMWHs, leading to an increased risk of hemorrhagic complications. Evaluation of trough anti-factor Xa activity at the end of the dosing interval can assess this accumulation effect and may be considered for patients with severe renal dysfunction.[10] LMWHs are dosed according to total body weight, but clinical trials have included only limited numbers of obese patients. Routine monitoring of anti-factor Xa activity in patients is not suggested for obese and nonobese patients.[10] Anti-factor Xa activity may also be evaluated in patients who experience unexpected bleeding complications secondary to anticoagulation with LMWHs, and in pregnant patients in whom LMWHs are used for treatment or prevention of thrombosis.

Anti-factor Xa activity is measured using a chromogenic assay. If peak activity levels are used to assess dosing in obese and pregnant patients, they should be obtained once the patient has reached steady state, typically after three or four doses of LMWH. The anti-factor Xa level should be drawn ~4 hours after an SC dose of LMWH, with empiric dosing adjustments to maintain a level of roughly 0.5 to 1.0 IU/mL for therapeutic anticoagulation given every 12 hours, and slightly higher peaks up to 1.5 for therapeutic doses given every 24 hours.[3,9] However, there is little correlation between peak anti-factor Xa activity and therapeutic effect, and thus monitoring is not routinely recommended.[10] Trough anti-factor Xa levels are expected to be <0.4 IU/mL at the end of the dosing interval. As with other measures of hemostasis, results vary considerably, requiring both instrument-specific and method-specific determination of therapeutic ranges.

DEEP VEIN THROMBOSIS

Clinical Presentation

SIGNS AND SYMPTOMS

CASE 11-1

Question 1: J.T., a 60-year-old, overweight (202.83 pounds [92 kg], 72-inch [182.88 cm] tall) male, was admitted to the hospital 3 days ago for management of acute cellulitis of his left ankle that occurred after cutting himself with a lawn tool a week ago. He was started on IV antibiotics and had limited mobility in the hospital owing to the pain at the wound site and is being evaluated by orthopedics for possible osteomyelitis and surgical intervention. On the third day of hospitalization, while the wound was improving, he noted progressive swelling and soreness of the left calf and around his left knee. He denied shortness of breath (SOB), cough, or chest pain. His medical history includes coronary artery disease, diabetes, and hypercholesterolemia. His medications are lisinopril 10 mg/day orally (PO), isosorbide mononitrate 120 mg/day PO, atenolol 50 mg/day PO, aspirin 81 mg/day PO, metformin 1000 mg PO twice daily, and atorvastatin 80 mg PO every evening. Initial laboratory values include:

Hct, 36.5%
PT, 10.8 seconds (INR, 1.0)
aPTT, 23.6 seconds
Platelet count, 255,000/μL

What signs and symptoms demonstrated by J.T. are consistent with DVT?

Patients with DVT typically present with unilateral leg swelling that often is accompanied by warmth and local tenderness or pain.[10] A tender, cordlike entity caused by venous obstruction can sometimes be palpated in the affected area. J.T. presented with the sudden onset of swelling along with soreness, but without evidence of a cord. Discoloration of the affected limb, including pallor from arterial spasm, cyanosis from venous obstruction, or a reddish color from perivascular inflammation, may also occur. The presence or absence of a positive Homan sign (pain behind the knee or calf on dorsiflexion of the foot) is rarely helpful in making the diagnosis because it is present in only about 30% of patients with DVT. Many

patients (>50%) can present with asymptomatic disease, but even asymptomatic patients can have long-term complications such as recurrent DVT or postthrombotic syndrome. Because symptoms of DVT are nonspecific, the diagnosis must be confirmed by objective testing.[14,15]

RISK FACTORS

Case 11-1, Question 2: What risk factors associated with DVT does J.T. exhibit?

The diagnosis of DVT depends not only on the presenting signs and symptoms but also on the presence of risk factors (see Fig. 11-1). J.T. has presented with obesity and immobilization (ie, prolonged bed rest), two important risk factors for thromboembolism, as well as an acute medical illness. It is common for more than one risk factor to be present in patients who exhibit DVT, and these factors are cumulative in their effect.[16]

DIAGNOSIS

Case 11-1, Question 3: How should the final diagnosis of DVT be made in J.T.?

After evaluation of the signs and symptoms of DVT and consideration of risk factors for the development of thrombus, a definitive diagnosis should be made. Diagnostic strategies should include an assessment of pretest clinical probability (clinical suspicion), D-dimer assay (an evaluation of the presence of fibrin degradation products, indicative of clot formation; see Chapter 2, Interpretation of Clinical Laboratory Tests), and noninvasive imaging tests.[14,15]

Despite its limitations as a single diagnostic tool, clinical assessment can improve the diagnostic accuracy of noninvasive testing. A clinical prediction rule, such as the Wells criteria, takes into

account signs, symptoms, and risk factors to categorize patients as being at low, intermediate, or high probability of having DVT (https://www.mdcalc.com/wells-criteria-dvt).[17] The D-dimer test can be used in conjunction with clinical evaluation or a clinical prediction rule to help "rule out" DVT in patients with a low clinical suspicion and thus decrease the need for imaging tests in these patients.[15] If the clinical suspicion of DVT is high, diagnostic imaging is indicated, and if the imaging is negative, the D-dimer is helpful to rule out the diagnosis.[14]

The most common noninvasive test is duplex scanning, which combines B-mode imaging or color flow imaging with Doppler ultrasonography to visualize veins and thrombi while investigating flow patterns. Other noninvasive testing options include iodine 125 (^{125}I)-fibrinogen leg scanning (injection of radiolabeled fibrinogen followed by scanning to detect areas of accumulation corresponding to thrombosis), impedance plethysmography (use of pneumatic cuffs to detect leg blood volume changes associated with thrombosis), and Doppler ultrasonography alone (use of a transducer to audibly detect venous flow changes indicative of thrombosis). Each option differs with respect to sensitivity, specificity, and cost. Venography (radiographic visualization of the involved vessels with injection of radiocontrast material), an invasive diagnostic test, was previously considered the most sensitive and specific method for diagnosis of DVT but is no longer routinely recommended because it exposes patients to the risks associated with contrast material, and is not readily available in many hospitals.[15]

Treatment

BASELINE INFORMATION

Case 11-1, Question 4: What additional baseline data should be obtained before administering anticoagulants to J.T.?

In addition to assessing the integrity of the clotting process with platelet count, Hgb/Hct, PT, and aPTT, the patient's baseline renal function should be evaluated and documented because some anticoagulants are renally eliminated. Baseline values are used for comparison with the parameters that will be used in monitoring both therapeutic and adverse effects of anticoagulant therapy.

INITIATION OF THERAPY

Case 11-1, Question 5: Duplex scanning reveals clot formation in J.T.'s left calf extending to the left thigh. He does not exhibit signs of PE. What is the appropriate therapy for J.T., and how should it be initiated?

Prompt and optimal anticoagulant therapy is indicated to minimize thrombus extension and its vascular complications, as well as to prevent PE. Acute anticoagulation treatment options include injectable IV UFH initiated with a loading dose followed by a continuous infusion, adjusted-dose SC UFH, SC LMWH, or SC fondaparinux.[18] Alternatively, initial treatment with oral rivaroxaban or apixaban can be selected, without any initial parenteral anticoagulation. LMWH or UFH may be continued as monotherapy or transitioned to treatment with a VKA, dabigatran, or edoxaban. Because J.T. is currently hospitalized and may need further surgical procedures, IV UFH is selected for initial treatment of his DVT.

HEPARIN

Loading dose

Case 11-1, Question 6: J.T.'s medical resident ordered a heparin bolus dose of 5000 IU IV, to be followed by a continuous infusion of 1000 units/hour. Is this heparin dosing regimen appropriate?

A loading dose of heparin is required for several reasons. Based on pharmacokinetic principles, a therapeutic serum level will be achieved more quickly; thus, pharmacodynamic and therapeutic

responses to help prevent progression of the clot will occur rapidly. Second, a relative resistance to anticoagulation exists during the active clotting process. Therefore, a larger initial dose generally is necessary to achieve a therapeutic effect.

Although standardized doses of heparin for initiation of therapy (ie, 5000 units loading dose; 1000 units/hour maintenance dose) were used historically, this approach can result in significant delays in reaching a therapeutic intensity of anticoagulation. Body weight represents the most reliable predictor of heparin dosing requirement. For patients who do not have extremes of body weight (ie, <363.763 pounds [165 kg]), the use of the actual body weight (ABW) has been recommended to calculate the initial UFH dose.[10] For patients >363.76 pounds (165 kg), the use of the ABW is controversial, and the use of an adjusted-dosing weight is recommended by some experts.[10] Options include two different "dosing weight" calculations:

$$\text{Ideal Body Weight (IBW)} + 0.3 \times (\text{ABW} - \text{IBW}) \quad \textbf{(Eq. 11-2)}$$

or

$$\text{IBW} + 0.4 \times (\text{ABW} - \text{IBW}) \quad \textbf{(Eq. 11-3)}$$

Compared with standardized dosing, weight-based dosing (80 units/kg loading dose; 18 units/kg/hour initial infusion rate) increases the frequency of therapeutic aPTT at 6 and 24 hours, and decreases the risk of recurrent VTE.[19–21]

Initial heparin loading doses of 60 to 100 units/kg followed by an infusion rate of 13 to 25 units/kg/hour are commonly recommended.[22] Selection of the lower or upper dosage range is guided by the severity of the patient's symptoms and his or her potential sensitivity to adverse effects. For this 202.83-pound (92-kg) patient, a midrange loading dose of 7400 units (202.83 pounds [92 kg] × 80 units/kg), followed by a continuous infusion of 1700 units/hour (202.83 pound [92 kg] × 18 units/kg/hour), is recommended. Loading doses are typically rounded to the nearest

500 units and maintenance infusion rates to the nearest 100 units for convenience of administration.

Dose adjustments

Case 11-1, Question 7: The orders for J.T. were rewritten by his attending physician. Based on data shown subsequently, what are potential explanations for the variability in laboratory results? (At this institution, aPTT values of 60–100 seconds correspond with heparin plasma concentrations of 0.3–0.7 units/mL determined by anti-factor Xa assay.)

Time	aPTT (seconds)	Heparin Dosage Order
0800	31	(baseline) 7400 units bolus followed by 1700 units/hour infusion
0900	130	Hold infusion for 30 minutes, then to 1500 units/hour
1500	40	Rebolus with 2400 units, then to 1700 units/hour
2100	85	Continue at 1700 units/hour; recheck aPTT every morning

Although the aPTT drawn 1 hour after the initiation of the maintenance infusion (9:00 AM) demonstrates excessive prolongation of the aPTT (130 seconds), this value is most likely explained by inappropriate timing of the test. When aPTT values are drawn too soon after a heparin bolus dose (ie, before the maintenance infusion has achieved a steady-state concentration in serum), they are predictably very high, but are not associated with a bleeding risk and do not accurately reflect the anticipated level of anticoagulation in the patient. To ensure accuracy, the clinician should obtain aPTT values no sooner than 6 hours after a bolus dose or any change in the infusion rate. Even results obtained at 6 hours may be excessively prolonged in some patients because of the dose-dependent pharmacokinetic characteristics of heparin.

J.T.'s heparin dose was decreased at 9:00 AM based on this prolonged, yet inappropriately timed, value. A repeat aPTT at 3:00

PM was only 40 seconds. The decrease in the dosage to 1500 units/hour and the repeat aPTT of 40 seconds reflect near-steady-state conditions because 6 hours have elapsed since the dosage change. Because the aPTT was subtherapeutic at 3:00 PM (40 seconds), administration of a smaller repeat bolus dose (2000 units) and an increase in the maintenance infusion to 1700 units/hour was the correct course of action. Subsequent aPTT values reflected therapeutic anticoagulation.

Dosing nomograms or protocols have been recommended for adjustment of heparin dosing based on aPTT results.[3,10] Nomogram-based dosing reduces the time to reach therapeutic range compared with empiric dosing.[23] Attaining a therapeutic aPTT in <24 hours has been shown to lower in-hospital and 30-day mortality rates.[24] After initiation based on patient weight, dosing adjustments may also be weight based or may simply be made in international units per hour. A sample heparin dosing nomogram specific for a reagent with a therapeutic aPTT range of 60 to 100 seconds (and used in the adjustment of heparin doses for J.T.) is illustrated in **Table 11-10**.

Table 11-10
Sample Heparin Dosing Nomogram

1. Suggested loading dose
   - Treatment of DVT/PE: 80 units/kg (rounded to nearest 500 units)
   - Prevention, including cardiovascular indications: 70 units/kg (rounded to nearest 500 units)
2. Suggested initial infusion
   - Treatment of DVT/PE: 18 units/kg/hour (rounded to nearest 100 units)
   - Prevention, including cardiovascular indications: 15 units/kg/hour (rounded to nearest 100 units)
3. First aPTT check: 6 hours after initiating therapy
4. Dosing adjustments: per this chart (rounded to nearest 100 units)

aPTT[a] (seconds)	Heparin Bolus	Infusion Hold Time	Infusion Rate Adjustment	Next aPTT
<50	4000 units	0	Increase by 200 units/hour	In 6 hours
50–59	2000 units	0	Increase by 100 units/hour	In 6 hours
60–100	0	0	None	Every AM
101–110	0	0	Decrease by 100 units/hour	In 6 hours
111–120	0	0	Decrease by 200 units/hour	In 6 hours
121–150	0	30 minutes	Decrease by 200 units/hour	In 6 hours
151–199	0	60 minutes	Decrease by 200 units/hour	In 6 hours
>200	0	PRN	Hold until aPTT < 100	Every hour until <100

aPTT, activated partial thromboplastin time; DVT, deep vein thrombosis; PE, pulmonary embolism; PRN, as necessary.

[a]Based on activated partial thromboplastin time (aPTT) reagent-specific therapeutic range of 60 to 100 seconds corresponding to a plasma heparin

concentration of 0.3 to 0.7 units/mL determined by anti-factor Xa activity.

Responses to changes in infusion rates of heparin are not always linear, and, to some extent, heparin doses are adjusted by trial and error. As the patient's condition improves after several days and endothelialization of the clot occurs, heparin dosing requirements may decrease.

Therapeutic monitoring

Case 11-1, Question 8: How should J.T.'s heparin therapy be monitored?

Once baseline clotting parameters have been established and a loading dose of heparin has been administered, the aPTT should be measured routinely to guide subsequent dosing adjustments. The aPTT should be evaluated no sooner than 6 hours after the loading dose or after any changes in infusion rate, as noted previously. If dosing is stable, the aPTT should be evaluated once daily (Table 11-10).

Additional monitoring parameters for heparin therapy include evaluation for potential adverse reactions and possible therapeutic failure. The Hgb and/or Hct and a platelet count should be checked every 1 to 2 days. J.T. should be examined for signs of bleeding as well as for signs and symptoms associated with thrombus extension and PE. Finally, if unusual or unexpected aPTT results are reported, the clinician should consider the possible influence of solution preparation errors (see Chapter 2, Interpretation of Clinical Laboratory Tests), infusion pump failure, infusion interruption, and administration or charting errors in the assessment of J.T.'s heparin therapy.[25]

Duration of therapy

Case 11-1, Question 9: How long should heparin therapy be continued in J.T. if the patient starts warfarin?

Adherence of a thrombus to the vessel wall and subsequent endothelialization usually take 7 to 10 days. However, anticoagulation therapy must generally continue for 3 months to prevent recurrent thrombosis.[18] For many years, warfarin was preferred for this long-term anticoagulation because it can be administered orally, and it is generally initiated on the same day as heparin. The long elimination half-life of warfarin and the long elimination half-lives of clotting factors II and X necessitate a prolonged period of overlap between warfarin and heparin. Therefore, if warfarin is initiated, heparin is continued for a minimum of 5 days and until the INR is >2.0 for 24 hours. If the INR exceeds the therapeutic range (ie, INR >3.0) prematurely, it is acceptable to stop parenteral therapy before the patient has received 5 days of treatment.[18]

Case 11-1, Question 10: On day 2 of heparin therapy, J.T.'s complete blood count (CBC) reveals a platelet count of 180,000/μL, decreased from 255,000/μL at baseline. What is a reasonable explanation for this thrombocytopenia and how should it be managed?

Adverse effects

Thrombocytopenia

Thrombocytopenia induced by heparin has two distinct presentations.[5] Heparin-associated thrombocytopenia (HAT) occurs as a direct effect of heparin on platelet function, causing transient platelet sequestration and clumping with reductions in platelet count, but usually remaining >100,000/μL. This reversible form of thrombocytopenia occurs within the first several days of heparin therapy. Patients remain asymptomatic, and platelet counts return to normal even when heparin therapy is continued. J.T.'s reduction in platelet count is somewhat modest and likely represents HAT. His platelet count should be monitored daily, and heparin therapy should be continued.

Reductions in platelet count >50% from baseline suggest the development of HIT, a more severe immune-mediated reaction with

a typical delay in onset of 5 to 10 days after the initiation of heparin therapy. In contrast, “rapid-onset” HIT can occur rapidly (within 24 hours of UFH initiation) and is strongly associated with recent heparin exposure. And “delayed-onset” HIT is associated with an onset of thrombocytopenia that begins several days after heparin has been stopped.[5]

Heparin use leads to the formation of immunoglobulin G (IgG) antibodies that recognize multimolecular complexes of a platelet protein called platelet factor 4 (PF4) and heparin that forms on the surface of platelets.[5] Antibodies against PF4–heparin complexes are responsible for the prothrombotic nature of HIT owing to their capability to induce platelet activation by cross-linking platelet Fcc receptor IIa (CD32a),[26] and release procoagulant, platelet-derived microparticles, resulting in a large generation of thrombin and the formation of venous and arterial thromboses. The diagnosis of immune-mediated HIT is made based on clinical findings supplemented by laboratory tests confirming the presence of platelet-activating anti-PF4/heparin antibodies.[5,27,28] The 4T score is the most common pretest probability test and is recommended to estimate the likelihood of HIT based on extent and timing of platelet count reduction, the presence of thrombus, and the possibility of other causes of thrombocytopenia (**Table 11-11**).[5,27,29]

Table 11-11
The 4T Score: Pretest Probability of Heparin-Induced Thrombocytopenia

Category	2 Points	1 Point	0 Points
1. Thrombocytopenia	Platelet count fall >50% and platelet nadir ≥20 × 10^9 L^{-1}	Platelet count fall 30%–50% or platelet nadir 10–19 × 10^9 L^{-1}	Platelet count fall <30% or platelet nadir <10 × 10^9 L^{-1}
2. Timing of platelet count fall	Clear onset between days 5 and 10 or platelet fall ≤1 day (prior heparin exposure within 30 days)	Consistent with days 5–10 fall, but not clear (eg, missing platelet counts) or onset after day 10 or fall ≤1 day (prior heparin exposure 30–100 days ago)	Platelet count fall <4 days without recent heparin exposure
3. Thrombosis or other sequelae	New thrombosis (confirmed) or skin necrosis at heparin injection sites or acute systemic reaction after intravenous heparin bolus	Progressive or recurrent thrombosis or nonnecrotizing (erythematous) skin lesions or suspected thrombosis (not proven)	None
4. Other causes for thrombocytopenia	None apparent	Possible	Definite

Total score <3, low probability of HIT; 4–5, intermediate probability of HIT; >6, high probability of HIT.

Source: From Lo GK, Juhl D, Warkentin TE, Sigouin CS, Eichler P, Greinacher A. Evaluation of pretest clinical score (4 T's) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings. *J Thromb Haemost*. 2006;4(4):759–765. © 2006 International Society on Thrombosis and Haemostasis. Reprinted by permission of John Wiley & Sons, Inc.

The overall incidence of HIT is <3% after 5 days of UFH use, but the cumulative incidence can be as high as 6% after 14 days of continuous heparin use. Despite its low incidence, HIT is a life-threatening condition with a reported mortality rate of 5% to 10%. The condition in which patients have acute heparin-induced thrombocytopenia complicated by thrombosis is called *HITT*, whereas acute HIT without thrombosis is referred to as *isolated HIT*. Venous thrombosis is the most common complication secondary to HIT, with rates reported at 2.4 to 1 more common than arterial thrombosis (limb artery thrombosis, thrombotic stroke, and MI).[30] Limb gangrene has been reported at 5% to 10%, with a resulting risk of amputation.[31]

In patients who have acute HITT or isolated HIT, heparin therapy should be stopped immediately, and treatment with an alternative non-heparin anticoagulant should be initiated.[5,29] Although associated with a lower risk of HIT (<1%) than UFH, LMWH products are contraindicated in patients with HIT because of a high incidence of immunologic cross-reactivity with heparin.[5,29] The future use of heparin in patients with HIT, especially in the first 3 months after the diagnosis, should be avoided. Treatment options for patients with critical illness, increased bleeding risk, or increased potential need for urgent procedures include the direct thrombin inhibitors argatroban and bivalirudin, although only argatroban is approved for this indication by the FDA. The dose of argatroban is administered as an IV infusion because of its short half-life and should be titrated based on aPTT testing. Bivalirudin is a suitable alternative for the treatment of HIT owing to its short-half life, low immunogenicity, minimal effect on INR, and enzymatic metabolism. Various patient-related factors (such as the presence of renal or hepatic dysfunction;

drug availability, cost, and institutional preference) should be used to select the most appropriate agent[5,29] (Table 11-7). Although off-label and with limited data, the 2018 American Society of Hematology (ASH) Guidelines conditionally support the use of DOACs and fondaparinux in isolated HIT and acute HITT in stable patients at average risk for bleeding.[29]

CASE 11-1, QUESTION 11: On day 3 of heparin therapy, J.T.'s Hct has dropped from a baseline of 37.5% to 28%, and the patient noted blood in his commode after urination. What is an effective approach to evaluate and interpret this event?

Hemorrhage

Bleeding is the most common adverse effect associated with heparin. A summary of eight studies reporting heparin-associated bleeding found the absolute frequency of fatal, major, and all (major or minor) bleeding to be 0.4%, 6%, and 16%, respectively.[32] The corresponding average daily frequencies were 0.05% for fatal bleeding, 0.8% for major bleeding, and 2% for major or minor bleeding; cumulative risk increased with the duration of therapy. The most common sites for heparin-associated bleeding are soft tissues, the GI and urinary tracts, the nose, and the oral pharynx. The use of different criteria to define major versus minor bleeding accounts for much of the variability in reported frequency of bleeding among studies.

In addition to length of therapy, many factors influence the risk of bleeding during heparinization, including advanced age, serious comorbid illnesses (heart disease, renal insufficiency, hepatic dysfunction, cerebrovascular disease, malignancy, and severe anemia), and concomitant antithrombotic therapy.[32] The incidence of UFH-associated bleeding complications is minimal with SC prophylactic doses, but higher (2%–4%) with therapeutic doses given via IV infusion. Soft tissue bleeding commonly occurs at sites of recent surgery or trauma. Previously undiagnosed abnormalities, including malignancy and infection, may be identified in some

patients with GI or urinary tract bleeding associated with heparin therapy.

The influence of the intensity of heparinization on bleeding risk is controversial. Although an elevated aPTT has historically been considered a risk factor for bleeding complications, several investigators have been unable to substantiate a relationship between supratherapeutic aPTT values and hemorrhagic effects.[3] In addition, bleeding episodes can occur when coagulation test results are within the therapeutic range. These conflicting results may be explained in part by the influence of additional risk factors for bleeding and by the effect of heparin on platelet function and vascular permeability.

J.T. has developed hematuria despite an acceptable intensity of anticoagulation. He should be questioned and examined for the presence of nose bleeding (epistaxis), increased tendency to bruise (ecchymosis), bright red blood in the stool (hematochezia), black or tarry stool (melena), or coughing up of blood (hemoptysis). Blood pressure and pulse, both sitting and standing, should be obtained to determine whether orthostasis representing blood loss is present. A thorough evaluation of the urinary tract may reveal a previously unknown abnormality that will explain the bleeding episode. Although his concurrent low-dose aspirin therapy may increase the risk of minor bleeding complications, aspirin therapy would not be discontinued because of his history of coronary artery disease.

CASE 11-1, QUESTION 12: What other side effects of heparin should be considered in J.T.?

Osteoporosis

The development of osteoporosis has been associated with the administration of >20,000 IU/day of heparin for 6 months or longer.[33] Various mechanisms have been suggested, but the underlying pathophysiology of this rare adverse effect remains unclear. Affected patients may present with bone pain and/or radiographic findings suggestive of fractures. The possibility of osteoporosis should be

considered in patients receiving long-term, high-dose heparin therapy such as pregnant patients, postmenopausal females, and elderly patients.

Hypersensitivity Reactions

Other rarely occurring adverse effects associated with heparin include generalized skin reactions that can progress to necrosis, alopecia, and hypersensitivity reactions, resulting in hypotension, nausea, and SOB. In 2007, an increase in hypersensitivity reactions to heparin was attributed to oversulfated chondroitin sulfate in the heparin manufacturing process.[34]

Reversal of effect

CASE 11-2

QUESTION 1: K.G. is a 72-year-old female with a DVT that occurred during her hospital stay. On day 4 of heparin therapy, she received a full bag of 25,000 units of heparin during a 1-hour period as a result of an infusion pump malfunction. The infusion was stopped and within 30 minutes, she became diaphoretic and hypotensive. Bright red blood was evident on rectal examination, and a large retroperitoneal mass was noted.

How should the excessive heparin effect be reversed?

K.G. has definite signs of hemorrhage from the GI tract, a site of bleeding associated with considerable mortality. Heparin should be discontinued immediately, and treatment should include maintenance of fluid volume and replacement of clotting factors with whole blood, fresh frozen plasma, or clotting factor concentrates. If hemorrhage had not been present and the only manifestation of overdose had been a prolonged aPTT, administration of heparin simply could have been discontinued, permitting the effects to clear within a few hours.

Protamine can be used to neutralize heparin by forming an inactive protamine–heparin complex.[3] Protamine has a rapid onset of action, with effects lasting about 2 hours. Protamine sulfate is

infused slowly over 3 to 5 minutes, as a 1% solution at a dose of 1 mg for each 100 IU of heparin administered in the past 2 to 3 hours. The maximum single recommended dose of protamine is 50 mg, but doses may be repeated if bleeding persists. Response to protamine therapy can be assessed by a return of the aPTT to baseline. Adverse effects associated with protamine include systemic hypotension secondary to rapid administration; anaphylaxis characterized by edema, bronchospasm, and cardiovascular collapse; and catastrophic pulmonary vasoconstriction[35] (see Chapter 32, Drug Hypersensitivity Reactions).

CASE 11-3

Question 1: N.C. is a 32-year-old female who presents to the emergency department (ED) with right leg pain behind the right knee of 2-day duration. She denies recent injury, but her medication history reveals that she recently started combination oral contraceptive tablets. She has no significant medical history and has no family history of clotting disorders. A duplex ultrasound finding is positive for DVT and immediate anticoagulation is indicated.

What therapeutic alternatives to hospitalization for IV UFH are available for this patient?

Outpatient treatment of deep vein thrombosis

In the past, hospitalization with UFH was the initial treatment of choice for acute DVT; however, the ease of SC dosing and self-administration of LMWHs and fondaparinux made them practical treatment alternatives to UFH, and allowed for outpatient management while transitioning to therapeutic warfarin.[18] In addition, meta-analysis data suggest that LMWH therapy for acute VTE results in fewer deaths, major hemorrhages, and recurrent VTE when compared to UFH.[36] Based on these advantages, outpatient use of LMWH became a common approach to treatment of uncomplicated DVT in patients who transition to warfarin. Home treatment is safe and effective and is preferred for uncomplicated DVT treatment.[37] Fondaparinux can also be considered as an alternative treatment because it has been shown to be as effective

and safe as LMWH in the treatment of DVT.[38] In addition, weight-based SC UFH (initial dose of 333 IU/kg followed by 250 IU/kg every 12 hours) without routine aPTT monitoring while patients become therapeutic on warfarin is an alternative for the treatment of acute VTE.[39] Vials of UFH at a concentration of 20,000 IU/mL are used by the pharmacy or the patient to draw up the weight-based dose. Although routine aPTT monitoring is not necessary, platelet count monitoring during the first 2 weeks is required to evaluate the possible development of HIT.

For N.C. to be treated at home with LMWH, she or a family member must be willing and able to administer SC injections, and she must be able to return for frequent follow-up visits, particularly during the first few weeks while warfarin therapy is initiated. In addition, her health care insurance should cover the cost of the drug, or she must be able to pay out of pocket. Contraindications to outpatient treatment of VTE include a preexisting condition that requires hospitalization, clinical symptoms of PE with hemodynamic instability, and recent or active bleeding.

N.C. meets the eligibility requirements for home treatment of her DVT. However, DOACs are preferred over warfarin as the first-line agents for the initial treatment of DVT.[18,37] She is a suitable candidate for a DOAC and prefers to not have to perform self-injections of medication. Currently, there are two DOACs, rivaroxaban and apixaban, approved in the United States for monotherapy, and they do not require an initial period of parenteral anticoagulant. Advantages to the use of a DOAC compared to warfarin include the lack of routine monitoring for assessing drug efficacy, fewer drug and food interactions, and a lower rate of major bleeding compared to warfarin. Currently, dabigatran has an FDA-approved agent for reversal, idarucizumab, and rivaroxaban and apixaban can be reversed with andexanet-α.[40] When selecting a DOAC, it is important to know the patient's renal function because these agents have varying doses based on current renal function. A baseline CBC should also be checked, because all anticoagulants have the potential for bleeding, and it is important to know the baseline Hgb level in case bleeding occurs on treatment. Baseline LFTs are also

recommended because there are precautions with some of the DOACs in hepatic dysfunction (see Table 11-5). In this case, N.C. received an injection of LMWH while in the ED, and rivaroxaban is selected for monotherapy, at 15 mg twice daily with food for 21 days, followed by 20 mg daily with food for the remainder of her 3-month duration of treatment. N.C. should be advised to follow up with her primary care provider regarding her new diagnosis, and it should be stressed to the patient the importance of proper transitioning of the dose from the twice-a-day to the once-a-day schedule. Anticoagulation clinics may also be involved in N.C.'s care to follow up and make sure she was able to obtain the medication without insurance barriers, that the DOAC dose was appropriate, that her DVT symptoms are improving, that she is tolerating the medication, and that she transitions to the correct dose appropriately.[41,42] Higher risk patients, such as those with lower health literacy and multiple medical problems, may benefit from face-to-face clinical visits if this information cannot be obtained by telephone. Centralized anticoagulation management services are expanding beyond traditional monitoring to include patients on DOACs by prospectively following them up to ensure optimal therapeutic outcomes. There are some cases where it may be necessary to test whether the DOAC is present, such as in a patient with acute stroke, need for urgent surgery, or in the case of major bleeding.[43] Tests that are suitable for quantitation of DOACs are not often readily available. Of those that are readily available, a dilute thrombin time may be used to detect dabigatran presence, and the anti-factor Xa calibrated for the factor Xa inhibitors.[43] Tests that provide a suitable qualitative assessment of DOAC presence include thrombin time for dabigatran; and for the factor Xa inhibitors, a PT or an anti-factor Xa that is used for UFH or LMWH may be used.[43]

CASE 11-3, QUESTION 2: During a follow-up call to N.C. from the anticoagulation clinic the next morning, it is discovered that N.C. was not able to get the rivaroxaban filled at her pharmacy last night because her insurance does not cover any DOAC therapy without first documenting a treatment failure to warfarin. What alternative treatment is available for N.C.?

Before the DOACs, treatment with self-injected LMWH bridging to warfarin at home was the standard of care. Possible treatment options and doses for N.C. are listed in **Table 11-12**. In this case, enoxaparin is the LMWH preferred by her insurance because it is available generically. The usual dosing of enoxaparin for treatment of DVT is 1 mg/kg total body weight SC every 12 hours, rounded to the nearest 10-mg increment. Once-daily dosing at 1.5 mg/kg SC every 24 hours is also an option, but this strategy is inferior to twice-daily dosing in patients with malignancy or obesity.[44] N.C.'s medical history is suitable for the once-daily dose of enoxaparin, which is more convenient for administration. At 143.30 pounds (65 kg), a dose of 1.5 mg/kg would be 97.5 mg, which will be rounded to the nearest 10-mg increment. N.C. will therefore receive 100 mg SC every 24 hours. Warfarin therapy is initiated concurrently to expedite the conversion to oral treatment.

Table 11-12

Dosing of Low-Molecular-Weight Heparin and Fondaparinux for the Treatment of Venous Thromboembolism

Dalteparin	Enoxaparin	Tinzaparin	Fondaparinux
100 IU/kg SC every 12 hours *or* 200 IU/kg SC every 24 hours	1 mg/kg SC every 12 hours *or* 1.5 mg/kg SC every 24 hours	175 IU/kg SC every 24 hours	5 mg SC every 24 hours if weight <50 kg 7.5 mg SC every 24 hours if weight 50–100 kg 10 mg SC every 24 hours if weight >100 kg

SC, subcutaneously.

Because LMWHs are eliminated renally, patients with significant renal impairment require dose reductions to prevent drug accumulation and to minimize the risk of bleeding complications.[45] The degree of drug accumulation can vary between the various LMWH preparations, and thus specific guidelines for dose adjustments are agent specific (**Table 11-13**).[46] Routine monitoring of trough anti-Xa activity in patients with severe renal impairment that are treated with LMWH for an extended period of time (ie, >1 week) is not recommended.[10] Fondaparinux is also renally excreted and is contraindicated in patients with creatinine clearance <30 mL/minute.

Table 11-13

Dosing of Low-Molecular-Weight Heparins in Patients With Renal Impairment (CrCl <30 mL/minute)[a]

LMWH	Dalteparin	Enoxaparin	Tinzaparin
Product information recommendations	Use with caution.	Prophylaxis: 30 mg SC daily Treatment: 1 mg/kg SC daily	Use with caution.
Dosing suggestions based on agent-specific pharmacokinetic observations	CrCl <30 mL/minute[a]: No dose adjustment needed up to 1 week with prophylactic doses. For use >1 week, consider monitoring of trough anti-Xa activity and adjust dose if accumulation is noted. CrCl 30–50 mL/minute: No dose adjustment needed.	CrCl <30 mL/minute[a]: Consider a 40%–50% dose decrease and subsequent monitoring of trough anti-Xa activity. CrCl 30–50 mL/minute: Consider a 15%–20% dose decrease with prolonged use (>10–14 days) and subsequent monitoring of anti-Xa activity.	CrCl <30 mL/minute[a]: Consider a dose decrease of 20% and subsequent monitoring of trough anti-Xa activity. CrCl 30–50 mL/minute: no dose adjustment needed

[a]In patients with a creatinine clearance (CrCl) <30 mL/minute, data are very limited, and use of unfractionated heparin is suggested.

CrCl, creatinine clearance; LMWH, low-molecular-weight heparin; SC, subcutaneously.

N.C. should be educated regarding the potential adverse effects of LMWH therapy (bleeding, thrombocytopenia, pain, and bruising at the injection site), required laboratory monitoring, and the expected duration of anticoagulation. At baseline, Hgb and/or Hct, INR, serum creatinine (SCr), and platelet count should be determined. Platelets will continue to be monitored at least every 2 to 3 days while the patient is receiving LMWH therapy, to a maximum of 10 to 14 days. N.C. can expect to continue enoxaparin therapy for a minimum of 5 days. If by day 5 her INR is therapeutic and stable, enoxaparin can be discontinued. Oral anticoagulation with warfarin should be continued for 3 to 6 months.[18,37] N.C. should also be advised against further use of estrogen-containing contraceptives.[47]

To ensure the safety and efficacy of home treatment, N.C. should be provided with the names and telephone numbers of the health care providers who will assume responsibility for her care, including her primary physician and her anticoagulation management team. No patient should be sent home with LMWH without an adequate follow-up plan.

Prevention of Venous Thromboembolism

CASE 11-4

QUESTION 1: M.G., a 63-year-old obese male, is to undergo elective abdominal surgery for treatment of an umbilical hernia. He has a medical history significant for hypertension, currently controlled by enalapril 10 mg daily (blood pressure, 130/80 mm Hg), and gout, controlled with allopurinol 300 mg daily.

What therapeutic interventions might decrease the risk of DVT or PE in M.G.?

Surgical procedures represent a significant risk factor for DVT formation. However, all hospitalized patients, including both surgical and nonsurgical/medical patients, should be stratified for risk of VTE based on the presence of various factors.[16,48,49] There are several risk stratification scoring tools available for clinicians to evaluate a patient's individual risk for VTE, such as Caprini, international medical prevention registry on venous thromboembolism (IMPROVE), international medical prevention registry on venous thromboembolism with D-dimer (IMPROVEDD), and Padua scores.[50–53] These help clinicians select the most appropriate interventions to prevent DVT and reduce the risk of fatal PE, and include both mechanical and pharmacologic strategies.[54,55]

NONPHARMACOLOGIC MEASURES

Mechanical interventions aimed at preventing venous stasis and increasing venous return include the use of graduated compression stockings, as well as leg elevation, leg exercises, and early postoperative ambulation. Intermittent pneumatic compression (IPC) of the leg muscles, using inflatable cuffs applied to the calf and thigh, represents another alternative for the prevention of DVT.[16] In patients undergoing major surgery, IPCs have a conditional recommendation over graduated compression stockings.[55] Because it is generally less effective than is pharmacologic prophylaxis, mechanical prophylaxis is most commonly used in patients at high risk for bleeding, or as an adjunct to pharmacologic prophylaxis in patients at very high risk for VTE.

PHARMACOLOGIC MEASURES

Fixed, low-dose unfractionated heparin (LDUFH), administered as 5000 units SC every 8 to 12 hours depending on the indication, is an inexpensive and effective pharmacologic approach to DVT prevention in the setting of venous stasis in patients with acute medical illness, or after certain surgical procedures. Because LDUFH inactivates factor Xa without a direct effect on factor IIa, the aPTT is not prolonged, and therefore aPTT monitoring is unnecessary. Bleeding complications are minimized using this dosing regimen.

Fixed-dose SC LMWH and fondaparinux are alternative approaches for preventing DVT. Enoxaparin 30 mg SC every 12 hours or 40 mg SC once daily, dalteparin 2500 to 5000 IU SC once daily, and fondaparinux 2.5 mg SC once daily are effective strategies, although enoxaparin has been studied for a larger number of indications. The DOACs rivaroxaban, apixaban, and dabigatran have been FDA approved for DVT prophylaxis in patients undergoing orthopedic surgery. Betrixaban 160 mg as a single dose followed by 80 mg daily is approved for VTE prophylaxis in adult patients hospitalized for an acute medical illness, but it is no longer currently available in the United States. Current recommendations for prevention of VTE based on risk stratification are presented in **Table 11-14**.[54,55]

Table 11-14
Prevention of Venous Thromboembolism

Clinical Scenario	Recommendations
Major Surgery	Suggests the following: ▪ Pharm or mechanical prophy ▪ If do not receive pharm prophy, use mechanical prophy over no mechanical prophy ▪ Use IPC over GCS. ▪ Use combined prophy with mechanical and pharm prophy over pharm prophy alone. ▪ Depending on VTE and bleeding risk based on patient and surgery: Use combined prophy or mechanical prophy alone.

Clinical Scenario	Recommendations
	Suggests against IVC filters
	Suggests extended prophy (>3 weeks) over short-term prophy (<2 weeks) Suggests using early or delayed prophy (12-hour cutoff point between early and delayed)
Orthopedic surgery	THR or TKR: suggests ASA or anticoagulants. When anticoagulants used, suggests DOACs over LMWH. If DOAC not used, suggests LMWH over warfarin, and recommends LMWH over UFH
	Hip fracture surgery: suggests pharm over no pharm prophy Suggests LMWH or UFH
Major general surgery	Suggests pharm prophy over no pharm prophy Suggests LMWH or UFH
Laparoscopic cholecystectomy	Suggests against pharm prophy
Major neurosurgical procedures	Suggests against pharm prophy If pharm prophy used, suggests LMWH over UFH
Urologic procedures	TURP: suggests against pharm prophy If pharm prophy used, suggests LMWH or UFH
	Radical prostatectomy: suggests against pharm prophy If pharm prophy used, suggests LMWH or UFH
Cardiac or major vascular surgery	Suggests pharm prophy over no pharm prophy Suggests LMWH or UFH
Major trauma	Low to moderate risk of bleeding: suggests pharm prophy over no pharm prophy High risk for bleeding: suggests against pharm prophy If pharm prophy used, suggests LMWH or UFH
Major gynecologic surgery	Suggests pharm prophy over no pharm prophy Suggests LMWH or UFH

Clinical Scenario	Recommendations
Acutely ill medical patients	Suggests UFH, LMWH, or fondaparinux over no parenteral AC Suggests LMWH or fondaparinux over UFH Recommends LMWH over DOACs Recommends inpatient VTE prophy with LMWH only, over inpatient and extended-duration VTE prophy with DOACs Recommends inpatient over inpatient plus extended-duration VTE prophy
Critically ill medical patients	Recommends UFH or LMWH over no UFH or LMWH Suggests LMWH over UFH Recommends inpatient over inpatient plus extended-duration outpatient VTE prophy
Acute or critically ill medical patients	Suggests pharm prophy over mechanical prophy If not receiving pharm prophy, suggests mechanical prophy Suggests pharm or mechanical prophy alone over mechanical combined with pharm prophy Suggests IPC or GCS
Chronically ill medical or nursing home patients	Suggests not using VTE prophy over any VTE prophy
Medical outpatient with minor provoking risk factors	Suggests not using VTE prophy
Long-distance travelers	Without VTE risk factors: suggests not using GCS, LMWH, or ASA for VTE prophy Substantially increased VTE risk: suggests GCS or prophy LMWH Substantially increased VTE risk and LMWH or GCS not feasible: suggests ASA over no VTE prophy

AC, anticoagulation; ASA, aspirin; DOAC, direct oral anticoagulant (refer to Table 11-4 for DOAC dosing); GCS, graduated compression stockings; IPC, intermittent pneumatic compression; IVC, inferior vena cava; LMWH, low-molecular-weight heparin (enoxaparin 40 mg SC daily or 30 mg SC every 12 hours; dalteparin 2500–5000 IU SC; fondaparinux [2.5 mg SC daily]); pharm, pharmacologic; prophy, prophylaxis; TURP, transurethral resection of the prostate; UFH, unfractionated heparin (5000 international units [IU] subcutaneously [SC] every 8–12 hours); VTE, venous thromboembolism.

Sources: Schünemann HJ, Cushman M, Burnett AE, et al. American Society of Hematology 2018 guidelines for management of venous thromboembolism: prophylaxis for hospitalized and nonhospitalized medical patients. *Blood Adv*. 2018;2(22):3198–3225. doi:10.1182/bloodadvances.2018022954; Anderson DR, Morgano GP, Bennett C, et al. American Society of Hematology 2019 guidelines for management of venous thromboembolism: prevention of venous thromboembolism in surgical hospitalized patients. *Blood Adv*. 2019;3(23):3898–3944. doi:10.1182/bloodadvances.2019000975.

M.G. is at high risk for DVT and PE, not only because of general surgery but also because of his age (older than 40 years) and the presence of other risk factors for VTE (obesity and probable postoperative immobilization). Options for DVT prevention include SC heparin at 5000 IU every 8 hours or an LMWH (enoxaparin 40 mg SC daily, or dalteparin 2500 IU initial dose followed by 5000 IU SC daily). The first dose is generally given 12 or more hours postoperatively until he is fully ambulatory. If bleeding risk is of concern, IPC could be used as an alternative. VTE prophylaxis is typically continued until hospital discharge but may be continued for up to 30 days in certain high-risk populations, including patients with cancer, orthopedic surgery, bariatric surgery, or with a prior history of VTE.

CASE 11-5

Question 1: A.W. is a 52-year-old, 154.32-pound (70-kg) female. She recently returned from a 12-hour car ride during which she only stopped to stretch twice. Yesterday she noticed a swollen right calf that is painful and warm. This swelling gradually increased, affecting the entire right leg to the groin, and prompted her to seek medical attention. In the ED, she also notes the recent onset of right-sided pleuritic chest pain without SOB or hemoptysis. Her medical history includes a gastric ulcer 4 years ago, treated with proton-pump inhibitor therapy that has not recurred. Physical examination reveals an enlarged right leg and moderate tenderness in the entire leg. Chest examination reveals labored respirations, equal breath sounds, and no wheezing or crackles. Vital signs include blood pressure, 160/90 mm Hg; heart rate, 100 beats/minute; and respiratory rate, 28 breaths/minute and regular. Laboratory data include the following:

Hct, 26.7%
SCr 1.1 mg/dL

Arterial blood gases (on room air)
P_{O_2}, 72 mm Hg (normal, 75–100)
P_{CO_2}, 30 mm Hg (normal, 35–45)
pH 7.48 (normal, 7.35–7.45)

Chest CT shows a PE in the distal right main pulmonary artery extending into the right lower lobe. The electrocardiogram (ECG) shows sinus tachycardia. The lower extremity duplex ultrasound finding is positive for acute occluding thrombus from the right femoral vein all the way down to the soleal vein. Coagulation test results include the following:

PT, 11.2 seconds (INR, 1.0)
aPTT, 28 seconds
Platelet count, 248,000/μL

What subjective and objective evidence in A.W. is consistent with PE?

PULMONARY EMBOLISM

Clinical Presentation

SIGNS AND SYMPTOMS

The clinical diagnosis of PE is often difficult to make because of the nonspecificity of symptoms.[56] The most common symptoms of PE include tachypnea, cough, substernal and pleuritic chest pain, dyspnea, hemoptysis, fever, and unilateral leg pain. Signs and symptoms such as hypotension, tachycardia, presence of B-type natriuretic peptides (BNP) or NT-pro-BNP (N-terminal pro-brain natriuretic peptide), troponins (I or T), serum lactate, hypoxia, and ECG changes suggestive of right ventricular strain are important to recognize because these may indicate more severe thromboembolism and increased risk for 30-day mortality.[56] DVT precedes PE in ≥80% of patients. A combination of these signs and symptoms provides further evidence for acute PE.

DEFINITIONS

There are varying ways to define the severity of a PE. Some define PE based on a patient's in-hospital or 30-day risk for mortality, whereas other literature will cite terms such as massive and submassive PE.[56,57] Low-risk PE is classified as the presence of thromboembolism without changes in hemodynamics, right ventricular function, or cardiac biomarkers. These types of severity in patients can also be classified as small-to-moderate PE. High-risk PE is defined by the presence of shock (manifesting as tissue hypoperfusion, and hypoxia, cool clammy extremities, alterations in consciousness) or hypotension, specifically defined as a systolic blood pressure <90 mm Hg or a ≥40 mm Hg drop in systolic blood pressure for >15 minutes that is not attributed to new-onset arrhythmia, hypovolemia, or sepsis. These patients can also be classified as having massive PE.[57] Patients with right ventricular dysfunction characterized by echocardiographic evidence or by positive cardiac biomarkers (BNP >90 pg/mL or NT-pro BNP >500 pg/mL, troponin I >0.4 ng/mL, troponin T >0.1 ng/mL) are classified as having submassive PE if they are hemodynamically stable.[57]

DIAGNOSIS

Because the clinical signs and symptoms of PE are difficult to distinguish from many other medical conditions, further evaluation is necessary.[15,56] Chest radiograph, ECG, and arterial blood gas (alveolar–arterial oxygen gradient) abnormalities are often present in patients with PE, but as with clinical signs and symptoms, they are somewhat nonspecific. Pulmonary imaging is necessary to diagnose or definitely rule out PE. Although many methods are clinically available for chest imaging, the computed tomographic (CT) pulmonary angiography and ventilation–perfusion lung scanning ($\dot{V}/\dot{Q}$ scan) are the most common tests used for the diagnosis of PE, with the multidetector computed tomography (MDCT) being the imaging test of choice because of its ability to visualize the pulmonary arteries in the greatest detail. Lung scans that incorporate an assessment of perfusion, or regional distribution of pulmonary blood flow, and ventilation are referred to as $\dot{V}/\dot{Q}$ scans; they involve

both the injection and the inhalation of radiolabeled compounds. Test results are expressed as a high, intermediate, or low probability of PE. When ventilation (air movement) is normal over an area that shows abnormal perfusion (blood flow), a $\dot{V}/\dot{Q}$ mismatch exists, and PE is highly probable. If a matched defect is noted (abnormal ventilation over an area of abnormal perfusion), another disease state, such as chronic obstructive airway disease, is more likely.

As in the case of DVT, clinical assessment of PE can improve the diagnostic accuracy of noninvasive tests such as CT, MRI, or $\dot{V}/\dot{Q}$ scanning. Validated assessment tools can be used to stratify a patient's probability of a PE[58–61] (**Table 11-15**). In patients with a low clinical probability of PE, measuring a high-sensitivity D-dimer is recommended, and, if negative, PE can be ruled out, eliminating the need for further imaging studies.[15] In patients with a moderate-to-high clinical probability of PE, diagnostic imaging studies should be performed.

Table 11-15
Original and Simplified Pulmonary Embolism Severity Index (PESI) Scoring Systems

Parameter	Original Scoring Version (Points)	Simplified Scoring Version (Points)
Age	Points: age (years)	1 (if age >80 years)
Male sex	10	–
Cancer	30	1
Chronic heart failure	10	1[a]
Chronic pulmonary disease	10	1[a]
Heart rate >110 bpm	20	1
Systolic blood pressure <100 mm Hg	30	1
Respiratory rate >30 breaths/minute	20	–
Temperature <96.8 °F (36	20	–

°C)		
Altered mental status	60	–
Arterial oxygen saturation <90%	20	1
30-Day Mortality Risk (%)		
Very low: 0–1.6	Class I: <65	0 points: 1%
Low: 1.7–3.5	Class II: 66–85	
Moderate: 3.2–7.1	Class III: 86–105	
High: 4–11.4	Class IV: 106–125	≥1 point: 10.9%
Very high: 10–24.5	Class V: >125	

bpm, beats per minute; mm Hg, millimeters of mercury.

[a]Only 1 point can be obtained for chronic heart failure and/or chronic pulmonary disease. Patients with both of these comorbidities can obtain only 1 point.

Simplification of the pulmonary embolism severity index for prognostication in patients with acute symptomatic pulmonary embolism. *Arch Intern Med*. 2010;170:1383–1389.

Treatment

Case 11-5, Question 2: What anticoagulant strategy should be initiated for A.W.?

When the diagnosis of PE is suspected, anticoagulation should be initiated immediately while awaiting results of more definitive diagnostic procedures. There are several agents that can be used for the acute treatment of PE. IV UFH therapy initiated with a loading dose followed by a continuous infusion was the mainstay of therapy for many years. Now IV UFH is generally reserved for high-risk patients with PE in whom reperfusion therapy is being considered, patients with severe renal insufficiency, and in patients with severe obesity. For high- and intermediate-probability PE, weight-based LMWH or fondaparinux are preferred over IV UFH. LMWHs are

noninferior to UFH in the management of PE and are recommended over UFH in stable patients with PE because of their ease of use, less major bleeding, and ability for outpatient management or early discharge.[62,63] Fondaparinux demonstrated noninferiority when compared with IV UFH for rate of recurrent PE, with similar rates of major bleeding.[64] In addition, the DOACs have been evaluated for both the initial and long-term management of VTE, with dabigatran, rivaroxaban, apixaban, and edoxaban all FDA approved for the initial management of PE, and preferred over warfarin.[18,56] All of the DOACs were compared to LMWH/VKA and found to be noninferior for the rate of recurrent VTE.[65–69] Rivaroxaban and apixaban were studied as monotherapy, whereas patients on dabigatran and edoxaban were initially treated with at least 5 days of parenteral therapy before receiving a DOAC. If A.W. is being kept in the hospital for observation because of the severity of her symptoms, UFH therapy could be started at a loading dose of 5600 units (80 IU/kg × 154.32 pounds [70 kg]), followed by continuous infusion of 1300 units/hour (18 units/kg/hour × 154.32 pounds [70 kg]). Monitoring of the aPTT would be used to adjust dosing to maintain treatment within the therapeutic range (see Table 11-10).

Alternatively, SC LMWH 70 mg every 12 hours (1 mg/kg every 12 hours × 154.32 pounds [70 kg]) or SC fondaparinux 7.5 mg daily may be given while transitioning the patient to warfarin (see Table 11-12). A.W. could receive fixed-dose enoxaparin 70 mg SC every 12 hours (1 mg/kg every 12 hours × 154.32 pounds [70 kg]) or dalteparin 15,000 IU SC every 24 hours (200 IU/kg, rounded to nearest syringe size). Use of initial therapies such as LMWH, fondaparinux, and DOACs allows for outpatient therapy and early discharge in hospitalized patients with acute PE. For patients with low-risk PE and home circumstances that are adequate, early discharge is suggested over standard discharge.[15]

Reperfusion therapy, which includes systemic thrombolytic therapy, percutaneous catheter-directed treatment, and surgical embolectomy reverses right ventricular dysfunction and restores pulmonary perfusion more rapidly than does anticoagulant therapy alone.[56] Systemic thrombolytic therapy is generally reserved for

patients with a high risk of mortality and a low risk of bleeding.[56] Percutaneous catheter-directed treatment provides localized delivery of fibrinolytics to the pulmonary thrombi and is an alternative invasive method for removal of pulmonary emboli. It is a less invasive approach compared to surgical embolectomy in patients who are not candidates for systemic thrombolytic therapy. For patients with moderate- to high-risk PE, surgical embolectomy or percutaneous catheter-directed treatment should be considered in case of hemodynamic deterioration on anticoagulation treatment as an alternative to systemic thrombolytic therapy.[56]

WARFARIN

Transition from injectable anticoagulant therapy

Case 11-5, Question 3: If A.W. is to start on warfarin, rather than on a DOAC, when should it be administered, and how should the transition from injectable anticoagulant therapy be accomplished?

As in the treatment of DVT, if warfarin is to be started, the use of heparin, LMWH, or fondaparinux therapy for PE treatment should be continued for at least 5 days and until warfarin therapy is therapeutic for at least 24 hours. Warfarin should be started on the first day of treatment and continued for 3 months, or longer if indicated. However, a delay in the initiation of warfarin may be acceptable in the setting of an anticipated extended hospitalization, recent or anticipated surgery or other invasive procedures, or a medical condition with the potential for uncontrolled bleeding.[37]

There are several reasons to overlap heparin/LMWH/fondaparinux and warfarin therapy.[6] The onset of warfarin activity depends not only on its inherent pharmacokinetic characteristics (half-life >36 hours) but also on the rate of elimination of circulating clotting factors. Although warfarin inhibits production of the vitamin K–dependent clotting factors, previously synthesized clotting factors must be eliminated at rates that correspond with their elimination half-lives (see Table 11-8). Approximately four half-lives are required

for these factors to reach a new steady state after their production is inhibited, so the effect of warfarin can be delayed for several days. Initial increases in the INR reflect only reductions in factor VII activity, but full anticoagulation with warfarin requires adequate suppression of factors II and X, which have significantly longer elimination half-lives. By overlapping a quick-onset injectable anticoagulant such as heparin/LMWH/fondaparinux with warfarin therapy, adequate anticoagulation can be continued until warfarin therapy reaches a therapeutic intensity.

In addition to suppressing the synthesis of the vitamin K–dependent clotting factors, warfarin also inhibits the formation of the naturally occurring anticoagulant protein C and its cofactor, protein S. In patients with congenital protein C or protein S deficiency, initial warfarin therapy can suppress these proteins to concentrations that may result in hypercoagulability with possible thrombus extension, unless concurrent heparin therapy provides adequate anticoagulation. To prevent these complications, heparin/LMWH/fondaparinux and warfarin therapy should overlap.

Heparin therapy has been observed to prolong the INR,[70] and warfarin can prolong the aPTT by several seconds.[71] Thus, interference with laboratory tests should be considered in the evaluation of the intensity of anticoagulation during the overlap of heparin and warfarin therapy.

Initiation of warfarin therapy

Case 11-5, Question 4: In an effort to discharge A.W. from the hospital as soon as possible, an initial dose of warfarin 10 mg PO every evening for 3 days has been ordered. Is such a “loading dose” reasonable? What are more effective approaches to initiating therapy?

Initiation of warfarin dosing is complex because dosing requirements vary significantly among individuals. Daily doses as low as 0.5 mg and as high as 20 mg or more may be required in individual patients to reach a therapeutic INR.[72] Two primary

methods for initiation of warfarin therapy are used.[73] The average daily dosing method relies on an understanding that although dosing requirements for warfarin vary significantly among patients, an average dosing requirement of 4 to 5 mg/day of warfarin is necessary to maintain an INR of 2.0 to 3.0 in most patients. When average daily dosing is used for initiation of warfarin therapy, patients are typically started at 4 to 5 mg daily, with dosing adjustments as necessary until the therapeutic goal is reached. However, patients who may be more sensitive to the effects of warfarin (**Table 11-16**) are expected to require lower dosages of warfarin. In these patients, therapy should be initiated at 1 to 3 mg daily, with subsequent dosing adjustments as necessary. Several dosing algorithms, using a 4- to 5-mg initiation dose, have been developed to aid with dosing decisions after the first few doses of warfarin have been administered.[74–76] Another popular dosing algorithm recommended by the American College of Chest Physicians (ACCP) for outpatients uses a 10-mg initiation dose for the first 2 days, with the INR on day 3 measured to guide dosing on days 3 and 4, and the INR on day 5 used to guide the next three doses[22,77] (**Fig. 11-4**). Although using this dosing algorithm helps achieve a therapeutic INR more quickly than using a 5-mg initial dose, these findings may not be generalizable to all patient populations because the patients evaluated were relatively healthy, young outpatients.[78] The 10-mg initiation dose may lead to overanticoagulation and heightened bleeding risk in elderly and ill patients with multiple medical problems.[79] Average daily dosing is often used to initiate therapy in ambulatory patients; in this case, the first INR should be evaluated within 3 to 5 days of initiation of warfarin therapy (**Table 11-17**). In hospitalized patients, it is more common to evaluate the INR daily during initiation of therapy.

Table 11-16

Factors That Increase Sensitivity to Warfarin

Age older than 75 years
Weight <45 kg

Clinical congestive heart failure
Clinical hyperthyroidism
Decreased oral intake
Diarrhea
Drug–drug interactions
Elevated baseline INR (>1.4)
End-stage renal disease
Fever
Hepatic disease
Hypoalbuminemia
Known CYP2C9 or VKORC1 variant
Malignancy
Malnutrition
Postoperative status

CYP, cytochrome P450; INR, international normalized ratio; VKORC1, vitamin K epoxide reductase complex 1.

	Days/dose (mg)	
Day-3 INR	3	4
<1.3	15	15
1.3–1.4	10	10
1.5–1.6	10	5

Flexible initiation of warfarin is an alternative approach for starting therapy that is based on evaluating the rate of increase in the INR and making daily dosing adjustments based on daily INR evaluation, with a goal of determining the eventual maintenance dosing requirement. A popular flexible initiation nomogram is readily cited.[79,80,81] Using this nomogram, warfarin can be initiated with either a 10-mg or a 5-mg starting dose, with daily dosing adjustments based on the rate of increase in the INR. Flexible initiation does not necessarily shorten the time to reach the goal INR, and initiating therapy with a 10-mg dose as described in some protocols may be associated with an increased risk of early overanticoagulation in

certain patients. Nonetheless, these methods offer a more individualized approach to initiation of therapy.

The baseline INR for A.W. was 1.0. Using a flexible initiation protocol, the first dose of warfarin should be 10 mg administered in the evening on the first day of hospitalization. Subsequent INR values obtained daily will guide dosing requirements until a therapeutic INR is reached. The order for warfarin 10 mg orally every evening for three doses should be discontinued and replaced with daily orders for warfarin and INR monitoring.

Intensity and duration of therapy

Case 11-5, Question 5: What is the goal INR for A.W., and how long should anticoagulation be continued?

In patients with DVT or PE, warfarin doses that prolong the PT to an INR of 2.0 to 3.0 are defined as regular intensity therapy. This therapeutic range is recommended to maximize the antithrombotic effect of warfarin while minimizing potential bleeding complications associated with excessive anticoagulation.[6] Once formed, venous clots adhere to the blood vessel wall. Thus, the first step in the resolution of a thrombus involves covering the clot with a layer of endothelial cells to prevent additional platelet aggregation at the site of vessel injury. This endothelialization process generally takes 7 to 10 days to be completed. Initial anticoagulant treatment is used to prevent clot extension while allowing adequate endothelialization to occur. Continued anticoagulation prevents further clotting.

The appropriate duration of warfarin therapy is based on the likelihood of a recurrent venous thromboembolic event and the risk of bleeding in each patient (see Table 11-9). Patients with unprovoked (idiopathic) DVT or PE should be treated for at least 3 to 6 months, but considered for indefinite therapy as their likelihood of having a recurrent event can be as high as 30% over 5 years.[18,37] Patients with DVT or PE associated with transient or reversible risk factors (provoked VTE) are usually treated for 3 to 6 months, as in

the case of A.W., whose VTE-provoking risk factor was a prolonged car ride, because the risk of recurrence is lower (~10% over 5 years). In cancer-associated thrombosis, first-line treatment consists of DOACs (in patients without gastric or gastroesophageal lesions), or LMWH (in patients with gastric or gastroesophageal lesions), with fondaparinux, UFH, and warfarin also being options. Considerations include individual patient bleeding risk, patient preferences, tolerability, and drug costs.[82–84]

Adverse effects

Case 11-5, Question 6: What possible adverse effects from oral anticoagulation therapy should be considered in A.W. and how should they be monitored?

Hemorrhage

Bleeding is the most common adverse effect associated with anticoagulation. A summary of experimental and observational inception cohort studies determined that the average annual frequency of fatal, major, and all (major or minor) bleeding in patients treated with warfarin was 0.6%, 3%, and 9.6%, respectively.[32] However, wide variation in bleeding frequencies has been reported, likely due to differences in patient characteristics, treatment protocols, and the definition and assessment of bleeding among trials.

The most common sites for anticoagulation-related bleeding are the nose, oral pharynx, and soft tissues, followed by the GI and urinary tracts. Hemarthrosis (bleeding into joint spaces) and retroperitoneal and intraocular bleeding represent less common hemorrhagic complications of anticoagulation therapy.[6] GI and urinary tract bleeding in anticoagulated patients is often caused by previously undiagnosed lesions. Menstrual blood flow may also be increased and prolonged in females taking anticoagulants. This problem may be clinically significant if there is an underlying

pathologic condition (ovarian cysts, uterine fibroids, or polyps) resulting in abnormal vaginal bleeding.

For VTE treatment, the DOACs rivaroxaban and apixaban both showed significantly lower rates for major bleeding in clinical trials compared to warfarin, whereas edoxaban and dabigatran showed comparable rates. A meta-analysis demonstrated no statistically significant differences for efficacy and safety associated with most treatment strategies used to treat acute VTE compared with the LMWH/VKA combination.[85] However, it showed that the UFH/VKA combination is associated with a higher rate of recurrent VTE and that rivaroxaban and apixaban demonstrated a lower risk of major bleeding.

Although it is uncommon, intracranial bleeding resulting in hemorrhagic stroke represents the most common cause of fatal bleeding associated with warfarin therapy. Rates of intracranial hemorrhage associated with anticoagulants have been estimated to range from 0.3% to 2%, and up to 60% are fatal.[6] The DOACs have been shown to be as effective as warfarin for stroke prevention in patients with atrial fibrillation and are associated with lower rates of intracranial hemorrhage and reduced all-cause mortality. However, all of the DOACs, except for apixaban, are associated with a 25% increased risk of GI bleeding.[86]

Many factors influence the risk of hemorrhagic complications associated with warfarin. The frequency of bleeding is higher in the first 3 months of therapy than during the subsequent months.[87] Unlike heparin, the intensity of anticoagulation with warfarin directly influences the risk of bleeding, including intracranial hemorrhage.[88] Other patient-specific variables that influence the risk of warfarin-associated bleeding include a history of GI bleeding, serious comorbid disease (including malignancy), and concomitant therapy with aspirin, clopidogrel, or nonsteroidal anti-inflammatory drugs (NSAIDs).[6]

Several bleeding risk scores are available, including HAS-BLED (*H*ypertension, *A*bnormal renal or liver function, *S*troke, *B*leeding, *L*abile INR, *E*lderly, *D*rugs and alcohol) and ATRIA (anticoagulation and risk factors in atrial fibrillation), which may identify patients at

higher risk for bleeding.[89,90] A meta-analysis showed that the HAS-BLED has the best evidence for predicting bleeding risk in atrial fibrillation.[91] None of these bleeding risk scores have been very effective at predicting risk of major or fatal bleeding in the first 3 months of anticoagulation for VTE, and none have performed well in the elderly in predicting major bleeding in the first 90 days of anticoagulation for VTE.[92–96]

Bleeding complications in A.W. can be minimized by careful attention to the signs and symptoms of bleeding by the patient and her caregivers, maintenance of the INR within the therapeutic range, avoidance of therapy with concomitant drugs known to increase the risk of bleeding or to increase the INR, and routine outpatient follow-up for INR monitoring and clinical assessment.

Skin Necrosis

Warfarin-induced skin necrosis is a rare but serious adverse effect of oral anticoagulation, occurring in ~0.01% to 0.1% of patients treated with warfarin.[97] Patients present within 3 to 6 days of the initiation of warfarin therapy with painful discoloration of the breast, buttocks, thigh, or penis. The lesions progress to frank necrosis with blackening and eschar. Skin necrosis appears to be the result of extensive microvascular thrombosis within SC fat and has been associated with hypercoagulable conditions, including protein C or protein S deficiency. In these patients, rapid depletion of protein C before depletion of vitamin K–dependent clotting factors during early warfarin therapy can result in an imbalance between procoagulant and anticoagulant activity, leading to initial hypercoagulability and thrombosis. Adequate use of injectable UFH, LMWH, or fondaparinux during initiation of warfarin can prevent the development of early hypercoagulability.

Warfarin therapy should be discontinued in patients who develop skin necrosis. However, subsequent warfarin therapy is not necessarily contraindicated if it is required for treatment or prevention of thromboembolic disease. In patients with protein C or protein S deficiency and a history of skin necrosis, warfarin therapy

can be restarted at low dosages if given with UFH/LMWH/fondaparinux. Therapy is maintained until the INR has been within the therapeutic range for 72 hours. Supplementation of protein C through administration of fresh frozen plasma also may be indicated.

Purple Toe Syndrome

Purple toe syndrome is a rarely reported adverse effect that typically occurs 3 to 8 weeks after the initiation of warfarin therapy and is unrelated to intensity of anticoagulation.[98] Patients initially present with painful discoloration of the toes that blanches with pressure and fades with elevation. The pathophysiology of this syndrome has been related to cholesterol microembolization from atherosclerotic plaques, leading to arterial obstruction. Because cholesterol microembolization has been associated with renal failure and death, warfarin therapy should be discontinued in patients who develop purple toe syndrome.

Patient education

CASE 11-6

QUESTION 1: E.N. is a 42-year-old male newly diagnosed with unprovoked DVT. He will be treated as an outpatient with enoxaparin 1.5 mg/kg SC daily and started on warfarin 5 mg PO daily using average daily dosing initiation. His primary care physician would like him to receive follow-up care in the medical center's pharmacist-managed anticoagulation clinic.

What are the benefits of formal anticoagulation management services?

One of the keys to successful oral anticoagulant therapy is appropriate outpatient management. In comparison with routine medical care, management of warfarin therapy by anticoagulation clinics is associated with significant reductions in bleeding and thromboembolic complications, with reductions in the rates of warfarin-related hospital admissions and ED visits, and with outcome-based cost savings for health care organizations.[99]

Specialized anticoagulation management services, often led by pharmacists, offer many benefits for the management of anticoagulation therapy, including improved dosing regulation, continuous patient education, early identification of risk factors for adverse events, and timely intervention to avoid or minimize complications, and have been widely recommended.[41,100] E.N.'s referral to a pharmacist-managed anticoagulation clinic is likely to improve his overall satisfaction with care and his clinical outcomes.

The availability of portable INR self-testing devices also allows the option of anticoagulation monitoring in the home setting. Patient self-testing and patient self-management of INRs have been suggested for suitable patients who have been well educated and have demonstrated competency to perform the tests.[41] For patients who may prefer this monitoring method, a structured education and follow-up program should be designed and integrated with the patient's provider or the anticoagulation management service.

Case 11-6, Question 2: At his initial visit to the anticoagulation clinic, E.N. will receive extensive education about his warfarin therapy. What information should be conveyed to him by his anticoagulation provider to ensure the safety and efficacy of warfarin therapy?

Successful warfarin therapy depends on the active participation of knowledgeable patients.[6] The anticoagulant effect of warfarin is influenced by various factors, and fluctuations in the intensity of the anticoagulant effect of warfarin can increase the risk of both hemorrhagic complications and recurrent thromboembolism. Pharmacists and other providers can improve adherence to the medication schedule, as well as ensure the safety and efficacy of warfarin therapy, by providing appropriate education to patients treated with this agent.

Key elements that form the basis of a thorough patient education program for anticoagulation therapy are listed in **Table 11-18**. This information may be conveyed through written teaching materials, recorded instruction, individual or group discussion, or a combination of these approaches. Many useful educational tools are available

from the manufacturers of the oral anticoagulants and from other noncommercial sources.

Table 11-18
Key Elements of Patient Education Regarding Oral Anticoagulation

Identification of generic and brand names
Purpose of therapy
Expected duration of therapy
Dosing and administration
Visual recognition of drug and tablet strength
What to do if a dose is missed
Recognition of signs and symptoms of bleeding
Recognition of signs and symptoms of thromboembolism
What to do if bleeding or thromboembolism occurs
Potential for interactions with prescription and over-the-counter medications and natural/herbal products
Limiting use of alcohol
Avoidance of pregnancy
Significance of informing other health care providers that patient is taking anticoagulation, and when to notify anticoagulation provider when invasive procedures are being scheduled
When, where, and with whom follow-up will be provided
Dabigatran only: Swallow whole, keep in original container, caution about potential for GI upset
Rivaroxaban only: Take with food (evening meal).
Warfarin only: importance of INR monitoring and expected frequency, consistency of vitamin K

GI, gastrointestinal; INR, international normalized ratio.

E.N. should receive extensive education about warfarin therapy in an individual teaching session or an organized education program. A wallet card, medical bracelet, or an alternative method of identifying him as a patient treated with warfarin should be provided. The health

care provider who assumes responsibility for his outpatient warfarin therapy will need to provide continuing reinforcement of the essential elements of medication information at each follow-up visit.

Case 11-6, Question 3: After receiving 6 days of enoxaparin therapy and six doses of warfarin 5 mg/day PO, E.N.'s INR is 2.4. Enoxaparin is discontinued and E.N. is instructed to continue his current dosage of warfarin. He is scheduled to return to the anticoagulation clinic in 1 week for reevaluation. At that time, his INR is 1.7. What factors might account for this change in the intensity of anticoagulation?

Factors that influence warfarin dosing

Patients should always be questioned about their understanding of the prescribed dose and their adherence to the prescribed regimen. Questions might include, "What dose of the medication have you been taking?" "What time of the day do you take your medication?" and "How many times in the past week did you miss a dose of your medication?" If there is no evidence of misunderstanding of the correct dose or of noncompliance, numerous other factors that are known to influence warfarin dosing requirements in individual patients during both initiation and maintenance phases of therapy should be considered. Changes in dietary vitamin K intake, underlying disease states and clinical condition, alcohol ingestion, genetic factors, and concurrent medications can significantly change the intensity of therapy, resulting in the need for dosing adjustments to maintain the INR within the therapeutic range. In a dosing cohort of 1015 patients on warfarin therapy, body surface area, age, target INR, amiodarone use, smoker status, race, current thrombosis, VKORC1 polymorphism 1639/3673 G.A, CYP2C9(*)3, and CYP2C9(*)2 were all independent predictors of warfarin therapeutic dose.[101]

Dietary Vitamin K Intake

The two primary sources of vitamin K in humans are the biosynthesis of vitamin K_2 (menaquinone) by intestinal bacteria and dietary intake

of vitamin K_1 (phytonadione). The U.S.-recommended daily allowance for vitamin K is 70 to 140 µg/day, and the typical Western diet provides ~300 to 500 µg/day.[102] Vitamin K is found in high concentrations in certain foods, including green leafy vegetables (asparagus, broccoli, Brussels sprouts, cabbage, cauliflower, collard greens, endive, kale, lettuce, parsley, spinach, and turnip greens), soy milk, certain oils, certain nutritional supplements, and multiple vitamin products.

Variations in vitamin K intake have been linked to INR fluctuations in patients taking warfarin.[103,104] In addition, diets high in vitamin K content have been associated with acquired warfarin resistance, defined as excessive warfarin dosing requirements to reach a therapeutic INR range.[105] Numerous cases have also been reported in which patients previously stabilized with warfarin experienced elevations in INR with or without hemorrhagic complications when dietary sources of vitamin K were eliminated. Conversely, reductions in INR with or without thromboembolic complications have been reported in patients in whom dietary sources of vitamin K have been added.

This data illustrates the potential clinical significance of dietary changes in patients taking warfarin. To minimize these potential effects, E.N. should be counseled to maintain a consistent intake of dietary vitamin K.[106] His final warfarin maintenance dose will be partially influenced by his typical diet. However, restriction of dietary vitamin K intake is unnecessary, except in cases of significant resistance to the anticoagulant effect of warfarin. E.N. should be aware of the types of foods and supplements that contain large quantities of vitamin K, and should be counseled to maintain a consistent diet, to avoid bingeing on foods high in vitamin K content, and to report significant dietary changes to his health care provider. Appropriate assessment and follow-up are essential to prevent hemorrhagic or thromboembolic complications that may arise from changes in INR resulting from dietary alterations.

Underlying Disease States and Clinical Conditions

The presence or exacerbation of various medical conditions can also influence anticoagulation status[73] (**Table 11-19**). Diarrhea-associated alterations in intestinal flora can reduce vitamin K absorption, resulting in elevations in INR. Fever enhances the catabolism of clotting factors and can increase INR. Heart failure, hepatic congestion, and liver disease can also cause significant elevations in INR because of a reduction in warfarin metabolism. End-stage renal disease is associated with decreased CYP2C9 activity, resulting in lower warfarin dose requirements.

Table 11-19
Warfarin Interactions With Disease States and Clinical Conditions

Clinical Condition	Effect on Warfarin Therapy
Advanced age	Increased sensitivity to warfarin because of reduced vitamin K stores and/or lower plasma concentrations of vitamin K–dependent clotting factors
Pregnancy	Teratogenic; avoid exposure during pregnancy.
Lactation	Not excreted in breast milk; can be used postpartum by nursing mothers
Alcohol use	▪ Acute ingestion: inhibits warfarin metabolism, with acute elevation in INR ▪ Chronic ingestion: induces warfarin metabolism, with higher dose requirements
Liver disease	▪ May induce coagulopathy by decreased production of clotting factors, with baseline elevation in INR ▪ May reduce clearance of warfarin
Kidney disease	Reduced activity of CYP2C9, with lower warfarin dose requirements
Heart failure	Reduced warfarin metabolism because of hepatic congestion
Nutritional status	Changes in dietary vitamin K alter response to warfarin.
Tube feedings	Decreased sensitivity to warfarin, possibly caused by changes in absorption or vitamin K content of nutritional supplements

Smoking and tobacco use	▪ Smoking: may induce CYP1A2, increasing warfarin dosing requirements ▪ Chewing tobacco: may contain vitamin K, increasing warfarin dosing requirements
Fever	Increased catabolism of clotting factors, causing acute increase in INR
Diarrhea	Reduction in secretion of vitamin K by gut flora, causing acute increase in INR
Acute infection/inflammation	Increased sensitivity to warfarin

CYP, cytochrome P450; INR, international normalized ratio.

The impact of changes in thyroid function on warfarin dose requirements is controversial.[107] It had been suggested that levothyroxine initiation accelerates clotting factor catabolism, enhancing warfarin's anticoagulation effect; however, a retrospective review did not show a difference in the mean warfarin dose/INR ratios before and after levothyroxine initiation, suggesting that no clinical interaction exists, and additional monitoring may not be necessary.[107,108]

Acute physical or psychological stress has been reported to increase INR. Increased physical activity has also been reported to increase the warfarin dosing requirement. Smoking can induce CYP1A2, which may increase warfarin metabolism in certain patients, resulting in increased dose requirements.[109] Owing to its high vitamin K content, chewing smokeless tobacco can suppress the INR response.[110]

Thorough education of patients taking warfarin should include detailed attention to recognizing the signs and symptoms of changes in underlying disease states and clinical conditions that can influence warfarin dosing requirements. They should be instructed to contact their anticoagulation management program whenever changes that might influence INR and warfarin dose requirement occur.

Alcohol Ingestion

Chronic alcohol ingestion has been associated with the induction of the hepatic enzyme systems that metabolize warfarin. Therefore, warfarin dosing requirements are sometimes higher in patients who are alcoholic. Conversely, acute ingestion of large amounts of alcohol can slow warfarin metabolism through competitive inhibition of metabolizing enzymes, leading to elevations in INR and an increased risk of bleeding complications.[6,106] It is believed that moderate intake of alcoholic beverages is not associated with alterations in the metabolism or the therapeutic effect of warfarin as measured by INR. Patients taking warfarin should be educated to limit their alcohol consumption to less than one to two alcoholic beverages per day. Chronic drinkers should be counseled to limit their drinking and maintain a regular pattern to avoid fluctuations in INR.[106] E.N. does not need to abstain from drinking alcoholic beverages in moderation, but he should be counseled to avoid the sporadic ingestion of large amounts of alcohol.

Conversely, alcoholic liver disease (ie, cirrhosis) can alter multiple hemostatic mechanisms and reduce the production of hepatic clotting factors. Decreased production and clearance of vitamin K–dependent clotting factors accounts for the prolonged PT and INR often seen in these patients. Therefore, an increased response to warfarin would be expected in patients with liver impairment. Worsening liver function is also a predictor of bleeding complications and patients with end-stage liver disease are at increased risk for bleeding. Before instituting warfarin therapy in these patients, the risks of bleeding associated with both the underlying liver disease and warfarin therapy must be weighed against the benefit of preventing thromboembolic events. If warfarin is indicated, the best approach would be to use a cautious initiation and dose titration approach by starting with lower doses and titrating up slowly to goal. Small increases in dosage should be made, if indicated, recognizing that the full effect of any dose adjustment may be delayed in patients with severe liver dysfunction. Monitoring for bleeding complications is essential, even at goal INR ranges, when warfarin is used in patients with liver dysfunction.

Genetic Factors

The CYP2C9 and VKORC1 genotypes have been associated with warfarin dose requirements, and dosing algorithms incorporating genetic and clinical information have been shown to be predictive of stable warfarin dose.[111] However, dosing algorithms that incorporate CYP2C9 genotype and VKORC1 haplotype along with other patient characteristics to predict warfarin maintenance doses showed mixed results in randomized, prospective clinical trials.[112–115] Based on current data failing to show a clear benefit, ACCP recommends against the routine use of pharmacogenetic testing for guiding doses of VKA (grade 1B).[22]

Case 11-6, Question 4: How should E.N. be assessed and evaluated at this clinic appointment?

At each clinic visit, E.N. should be assessed for signs and symptoms of bleeding, and for signs and symptoms of clot progression and/or recurrence. The accuracy and reliability of the INR test should be also considered. In addition, E.N. should be asked about missed or extra doses of warfarin, dietary changes (increases or decreases in vitamin K, alcohol use), medication changes, recent illnesses (such as nausea/vomiting/fever/chills/diarrhea), any recent falls, and any known upcoming procedures. Regardless of the INR result, all factors that may influence E.N.'s anticoagulation status should be evaluated carefully.

Dosing adjustments

Case 11-6, Question 5: After a thorough assessment, it is determined that E.N. has adhered to his prescribed warfarin dosage schedule and that there is no apparent explanation to account for his reduction in INR. How should his warfarin dosage be adjusted?

When over- or underanticoagulation is verified, an adjustment in warfarin dosing may be necessary. **Table 11-20** describes approaches to warfarin dosing adjustments for maintenance therapy. Typically, dosing adjustments of 5% to 20% of the total daily dose (or the total weekly dose) are appropriate to reach the therapeutic range.[116] Because warfarin does not follow linear kinetics, small adjustments in dose can lead to large INR changes, and thus large dose adjustments (ie, >20% increase or decrease of the total weekly dose) are not recommended. These maintenance dosing guidelines should only be applied to patients who have reached a steady-state dose and not in the initiation phase of therapy.

Table 11-20
Warfarin Dose Adjustment Nomogram for Maintenance Therapy

INR (Goal 2–3)	Suggested Change in Total "Weekly" Dose
<1.5	Give extra one-time daily dose and increase weekly dose by 10%–20%.
1.5–1.9	Increase weekly dose by 5%–15% (may give extra one-time daily dose).[a]
2.0–3.0	Maintain current dose.
3.1–4.0[b]	Hold up to one daily dose and decrease weekly dose by 5%–20%.[a]
4.1–5.0[b]	Hold up to two daily doses and decrease weekly dose by 10%–20%.[a]

[a]If transient cause identified, may need not increase/decrease weekly dose.

[b]Assumes no active bleeding.

Source: Warfarin Use in Adults: Clinical Care Guideline, University of Illinois Hospital and Health Sciences System.

Because E.N. is currently taking 5 mg daily, an adjustment of 15% would increase his dosage to ~5.5 mg/day. This dosing adjustment can be made by having him take one 5-mg tablet and half of a 1-mg tablet each day (same daily dosing) or by having him take 7.5 mg 2 days per week and 5 mg all other days of the week (alternate-day

dosing). Patient preference about breaking tablets in half, the likelihood of confusion about different tablet sizes, and potential confusion on taking different doses on different days of the week should be the primary considerations when selecting a dosing method.[117]

Frequency of follow-up

Case 11-6, Question 6: E.N. agrees to increase his warfarin dosage to 5.5 mg/day. A new prescription for 1-mg tablets is written for him, and he is instructed about the use of these tablets. When should his INR be reassessed and his anticoagulation status, including physical assessment, be reevaluated?

It will take several days for his INR to reach a new steady state because of the long elimination half-lives of both warfarin and the vitamin K–dependent clotting factors. His INR should be rechecked ~1 week after a dosing adjustment has been made. Once a stable dose has been reached, patient assessment and INR monitoring typically occurs every 4 to 6 weeks. However, if E.N. displays any signs of medical instability or nonadherence, a follow-up schedule of every 1 to 2 weeks is indicated (**Table 11-21**). For carefully selected patients with well-controlled INRs, recall frequencies up to 12 weeks can be recommended.[22,41] For patients taking warfarin with previously stable therapeutic INRs who present with a single out-of-range INR of ≤0.5 below or above therapeutic, continuing the current dose and testing the INR within 1 to 2 weeks is suggested, rather than changing the overall daily dose.[22]

Table 11-21
Frequency of International Normalized Ratio Monitoring and Patient Assessment During Warfarin Therapy

Initiation Therapy	
Inpatient initiation	Daily
Outpatient flexible initiation method	Daily through day 4, then within 3–5 days

Outpatient average daily dosing method	Within 3–5 days, then within 1 week
After hospital discharge	Within 3–5 days
First month of therapy	Every 1–4 days until therapeutic, then weekly
Maintenance Therapy	
Medically stable inpatients	Every 1–3 days
Medically unstable inpatients	Daily
After hospital discharge	If stable, within 3–5 days; if unstable, within 1–3 days
Routine follow-up in medically stable and reliable patients	Every 4–12 weeks
Routine follow-up in medically unstable or unreliable patients	Every 1–2 weeks
Dose held today for significant overanticoagulation	In 1–2 days
Dosage change today	Within 1–2 weeks
Dosage change <2 weeks ago	Within 2–4 weeks

Management of overanticoagulation

CASE 11-7

QUESTION 1: V.G., who has been taking warfarin for 3 years with good INR control, noted bright red blood after a bowel movement (hematochezia) that resolved and has not returned. In the ED, an INR of 5.6 was reported. Her Hct and Hgb were both within normal limits, as were her vital signs. A stool guaiac test result was positive, and multiple external hemorrhoids were detected.

How should this adverse effect of warfarin be treated in V.G.?

Management of overanticoagulation depends on the clinical presentation of the patient. In the case of an elevated INR without bleeding complications, interruption of warfarin therapy by holding one or two doses until the INR returns to the therapeutic range is usually sufficient.[22] Minor bleeding complications accompanied by an elevated INR can also be managed by withholding warfarin therapy

for a short period until bleeding resolves. In either case, the patient should be questioned to determine a possible cause for the overanticoagulation, including intake of extra doses of warfarin, changes in diet or alcohol intake, changes in underlying medical conditions, or the use of other medications. In some cases, no apparent explanation is identified. Depending on the cause, a reduction in the maintenance dosing of warfarin may be necessary.

The time required for INR to return to the therapeutic range after warfarin is withheld depends on several patient characteristics. Advanced age, lower warfarin maintenance dose requirements, and higher INR are associated with increased time for INR correction.[118] Other factors that can prolong the time for INR to return to the therapeutic range include decompensated heart failure, active malignancy, and recent use of medications known to potentiate warfarin.

Although previously recommended and commonly used, low-dose vitamin K in patients with elevated INR 4.5 to 10 and are not bleeding is not associated with a reduction in major bleeding, and is no longer routinely recommended.[22] However, patients with INRs >10 and are not bleeding may benefit from small doses of oral vitamin K 1 to 2.5 mg. The decision on whether to give vitamin K to patients who are not bleeding needs to be based on the patient's individual risk for bleeding and thrombosis.[22] An oral dose of 1 to 2.5 mg can correct overanticoagulation in 24 to 48 hours without causing prolonged resistance to warfarin therapy, a problem commonly seen with larger (10 mg) doses of vitamin K. Intramuscular administration is contraindicated owing to the risk of hematoma formation, and SC administration of vitamin K is not recommended because of variable absorption.[119]

IV doses of 0.5 to 1 mg of vitamin K can correct overanticoagulation within 24 hours.[6] This approach is also useful for reversal of therapeutic anticoagulation before invasive procedures and can be used to correct overanticoagulation in high-risk cases. IV vitamin K should be diluted in a minimum of 50 mL IV fluid and administered with an infusion pump over a minimum of 20 minutes to prevent flushing, hypotension, and cardiovascular collapse.[6]

Although these symptoms resemble anaphylaxis, the mechanism of this adverse response is unclear. It is not known whether it is caused by phytonadione or by the vehicle in which phytonadione is formulated. If this adverse reaction occurs, administration of epinephrine may be indicated as well as other standard measures to support blood pressure and maintain the airway.

Rapid reversal of warfarin therapy is indicated in the setting of major, life-threatening bleeding (ie, severe GI bleeding, intracranial hemorrhage). Fresh frozen plasma or factor concentrates to replace clotting factors will decrease the INR for 4 to 6 hours and should be administered as needed with careful monitoring of volume status.[22] Supplementation with high-dose IV vitamin K (10 mg) may also be indicated. Administration of IV vitamin K will reverse the effects of warfarin within 6 to 12 hours. However, if continued warfarin therapy is indicated when bleeding resolves, anticoagulation with heparin may be necessary for as long as 7 to 14 days until the effect of high-dose vitamin K is diminished and warfarin responsiveness returns.

Hematochezia may be an early sign of more serious bleeding, but in many cases, this condition is associated with minor bleeding episodes and identifiable causes such as hemorrhoids. In a reliable patient, holding the warfarin until the INR returns to a therapeutic level usually suffices, along with the addition of a bowel regimen to prevent straining with bowel movements, topical cream to minimize swelling and irritation, increased fluids, and/or increased fiber intake. Because V.G. appears to have only minor bleeding from the stool, is hemodynamically stable, and has a stable Hgb, withholding warfarin is appropriate. If the patient has never had a colonoscopy, then evaluation for the appropriateness of this test may be warranted.

Use in pregnancy

CASE 11-8

Question 1: M.P., a 25-year-old female, takes warfarin for chronic therapy for recurrent DVTs. She tells you today that she missed her menses and thinks she may be pregnant. A pregnancy test ordered today returned a positive result.

What effects might warfarin have on the fetus? Are UFH or LMWHs safer alternatives in this situation?

Warfarin and other coumarin anticoagulants cross the placental barrier and may place the fetus at risk for hemorrhage and teratogenic effects.[120,121] Up to 30% of pregnancies that involve exposure to coumarin result in abnormal liveborn infants, and up to 30% in spontaneous abortion or stillbirth. Congenital abnormalities such as stippled calcifications and nasal cartilage hypoplasia primarily occurred in infants born to mothers receiving warfarin during the first trimester of pregnancy, with the highest risk during weeks 6 to 12. Other abnormalities, involving the central nervous system and eyes, are more likely to occur when the mother is taking warfarin later in the pregnancy. In addition, because warfarin crosses the placenta, fatal bleeding complications may occur.

Females of childbearing age who require anticoagulation should be counseled about options for contraception. Patients who become pregnant while receiving warfarin should be informed of the risks of continued anticoagulation to the fetus, as well as the risk to themselves of discontinuing anticoagulation.

Other options for pregnant females who require anticoagulation include UFH and LMWHs.[120,121] Because these agents do not cross the placenta, they are preferred over warfarin for use in pregnancy. Many clinical trials have validated the safety and efficacy of UFH and LMWHs in the prevention and treatment of DVT and PE during pregnancy, with LMWH generally preferred to UFH for long-term management throughout pregnancy.[120–123] When used at full doses for the treatment of VTE during pregnancy, dosing must be adjusted throughout the pregnancy to account for the expected increase in the body weight of the mother and the reported increase in clearance of LMWH during pregnancy.[123] Selected current recommendations for use of anticoagulants in pregnancy are outlined in **Table 11-22**.

Table 11-22
Selected Recommendations for Anticoagulation During

Pregnancy

Clinical Situation	Antepartum Options	Postpartum
1. Prophylaxis: Prior VTE		
Low risk of recurrent VTE (single episode of VTE associated with transient RF not related to pregnancy or use of estrogen)	Clinical vigilance	Prophylactic or intermediate-dose LMWH or VKA (INR 2–3) for 6 weeks over no prophylaxis
Moderate/high risk of recurrent VTE (single unprovoked VTE, pregnancy- or estrogen-related VTE, or multiple prior unprovoked VTE not receiving long-term AC)	Prophylactic or intermediate-dose LMWH over clinical vigilance or routine care	Prophylactic or intermediate-dose LMWH or VKA (INR 2–3) for 6 weeks over no prophylaxis
On long-term VKA	Adjusted-dose LMWH or 75% of a therapeutic dose of LMWH throughout pregnancy, over prophylactic dose LMWH	Resumption of long-term AC
2. Prophylaxis: No Prior VTE		
Homo-FVL or prothrombin mutation and positive FH for VTE	Prophylactic or intermediate-dose LMWH	Prophylactic or intermediate-dose LMWH or VKA (INR 2–3) for 6 weeks over no prophylaxis
All other patients with thrombophilias who have positive FH for VTE	Clinical vigilance	Prophylactic or intermediate-dose LMWH or, in females who are not protein C or -S deficient, VKA (INR 2–3) over routine care
Homo-FVL or prothrombin mutation and no positive FH for VTE	Clinical vigilance	Prophylactic or intermediate-dose LMWH or VKA (INR 2–3) for 6 weeks over routine care

All other thrombophilias with no positive FH for VTE	Clinical vigilance	Clinical vigilance
Long-term oral anticoagulants for mechanical valve replacement	▪ Adjusted-dose SC UFH ▪ Adjusted-dose bid LMWH (adjusted to achieve manufacturer-recommended 4-hour postdose peak anti-factor Xa concentration) ▪ UFH or LMWH (as given earlier) until the 13th week, with substitution by VKA until close to delivery when UFH or LMWH is resumed	Long-term warfarin to prior INR goal with UFH/LMWH overlap until INR above the lower limit of therapeutic range

Adjusted-dose unfractionated heparin (UFH): UFH subcutaneous (SC) q12h in doses adjusted to target a mid-interval activated partial thromboplastin time (aPTT) into the therapeutic range.

Prophylactic LMWH: dalteparin 5000 units SC q24h, tinzaparin 4500 units SC q24h, or enoxaparin 40 mg SC q24h (at extremes of body weight modification of dose may be required).

Intermediate-dose LMWH: dalteparin 5000 units SC q12h, enoxaparin 40 mg SC q12h.

Adjusted-dose LMWH: weight-adjusted, full treatment doses of LMWH, given once or twice daily: dalteparin 200 units/kg daily, tinzaparin 175 units/kg daily, dalteparin 100 units/kg q12h, or enoxaparin 1 mg/kg q12h.

AC: anticoagulation; bid, two times daily; FH, family history; FVL, factor V Leiden mutation; INR, international normalized ratio; LMWH, low-molecular-weight heparin; RF: risk factor; SC, subcutaneous; UFH, unfractionated heparin; VKA: vitamin K antagonist; VTE, venous thromboembolism.

VTE, thrombophilia, antithrombotic therapy, and pregnancy: antithrombotic therapy and prevention of thrombosis, 9th ed: American College of Chest Physicians evidence-based clinical practice guidelines. *Chest*. 2012;141(2 suppl):e691S–e736S. © 2012 The American College of Chest Physicians. With permission.

After being informed of the risks associated with warfarin, M.P. decided to continue her pregnancy and to begin anticoagulation with LMWH. Because pregnant females were excluded from clinical trials with the DOACs owing to their increased risk for maternal and fetal bleeding, their use in pregnancy is not recommended at this time. Warfarin therapy should be discontinued immediately and LMWH initiated using SC treatment doses as previously described. Dosing adjustments may be required throughout pregnancy based on changes in body weight and clearance, and the routine use of anti-factor Xa monitoring is not recommended. Potential adverse effects of LMWH use, including hemorrhage, thrombocytopenia, and osteoporosis, should be monitored appropriately.

For females desiring spinal anesthesia during delivery, treatment doses of LMWH should be discontinued a minimum of 24 hours before induction of labor, cesarean section, or placement of an epidural catheter, and restarted no sooner than 24 hours postoperatively, and with adequate hemostasis in place.[124] Neuraxial anesthesia should not be used in females on anticoagulation therapy (ie, within 24 hours of the last treatment dose of LMWH, or for patients receiving IV UFHs that have prolonged aPTTs). In patients not receiving epidural catheters, postpartum anticoagulation may be started 12 to 24 hours after delivery as long as there are no bleeding concerns.[124] Consider IV UFH in females at high risk for bleeding, with LMWH reasonable for most females. Restart warfarin when hemostasis has occurred, bridging with UFH or LMWH until the INR is therapeutic. Warfarin, LMWH, and UFH do not accumulate in breast milk and do not induce an anticoagulant effect in the infant and may be used in females who breast-feed[120]; therefore, M.P. can safely breastfeed. The DOACs are not currently recommended during breast-feeding.[121,123]

PREVENTION OF CARDIOGENIC THROMBOEMBOLISM

Atrial Fibrillation

ANTICOAGULATION BEFORE CARDIOVERSION

CASE 11-9

QUESTION 1: T.S., a 66-year-old female with hypertension and no other significant past medical history, presents to the cardiology clinic reporting of several days of fatigue and a "racing heart." On physical examination, her pulse is irregularly irregular, and her heart rate is 120 beats/minute. Using ECG, a diagnosis of atrial fibrillation is made and cardioversion planned.

Should T.S. be anticoagulated before cardioversion?

In atrial fibrillation, atrial activity and atrial enlargement cause stasis of blood within the atria and the left atrial appendage (LAA), which can result in atrial thrombus formation. Atrial thrombus formation increases the risk of systemic embolization; clinical manifestations include arterial embolization of the extremities or embolization of the splenic, renal, or abdominal arteries. However, the most prevalent site of embolization is the cerebral arterial system, resulting in transient ischemic attack (TIA) or stroke with potentially devastating neurologic and functional impairment. Atrial fibrillation carries a fivefold risk of ischemic stroke without thromboprophylaxis.[125]

Both direct current cardioversion and pharmacologic cardioversion using antiarrhythmic drugs expose patients to an initial short-term increase in stroke risk from embolization secondary to resumption of normal atrial mechanical activity (see Chapter 15, Cardiac Arrhythmias). Data from a prospective cohort study of 437 patients noted a stroke incidence of 5.3% in patients with atrial fibrillation who were cardioverted without prior anticoagulation, but a significant reduction in stroke incidence to 0.8% was noted if patients who had received cardioversion were anticoagulated.[126] In addition to preventing the development of new atrial thrombi, anticoagulation allows any thrombus that may be present to endothelialize and adhere to the atrial wall so that the thromboembolic risk is minimized. Based on the assumed time course of thrombus

development, as well as the presumed time course of clot endothelialization, patients who have been in atrial fibrillation for >48 hours or of unknown duration should receive 3 weeks of therapeutic anticoagulation with either warfarin to a target INR of 2.5 (range, 2.0–3.0) or a DOAC (dabigatran, rivaroxaban, apixaban, or edoxaban).[125,127] Despite a lower risk of stroke than that associated with atrial fibrillation, patients with atrial flutter should be treated similarly.

Whether T.S. has been in atrial fibrillation for 48 hours is not known; therefore, she requires a 3-week course of oral anticoagulation before cardioversion is attempted. If T.S. cannot tolerate her heart symptoms despite control of the ventricular response rate, her medical team might consider immediate cardioversion without anticoagulation if transesophageal echocardiography (TEE) is used to rule out left atrial thrombi. TEE is much more sensitive than is transthoracic echocardiography (TTE) to visualize the left atrium and the LAA.

In a clinical trial, 1222 patients with atrial fibrillation for a duration of ≥2 days were randomly assigned to either cardioversion guided by TEE or to conventional anticoagulation before cardioversion.[128] Patients assigned to conventional treatment and patients in the TEE group in whom thrombus was detected received a 3-week course of warfarin before cardioversion. Patients without detectable thrombus by TEE were cardioverted without prior anticoagulation. All patients received 4 weeks of postcardioversion anticoagulation. Thromboembolic rates were identical between patients who received conventional treatment and those whose treatment was guided by TEE.[128]

ANTICOAGULATION AFTER CARDIOVERSION

Case 11-9, Question 2: After 3 weeks of regular intensity warfarin therapy, T.S. is successfully cardioverted to normal sinus rhythm. Should anticoagulation be discontinued?

Despite normalization of atrial electrical activity, restoration of effective atrial mechanical activity after cardioversion of atrial fibrillation can be delayed for up to 3 weeks. In addition, many patients who are cardioverted successfully will revert to atrial fibrillation during the first month. These factors contribute to the recognized delay in stroke presentation after cardioversion in patients with atrial fibrillation. Therefore, anticoagulation should be continued after cardioversion for a minimum of 4 weeks. Longer duration of anticoagulation therapy should be based on the individual patient's thromboembolic risk profile.[125,127]

CASE 11-9, QUESTION 3: Two weeks after successful cardioversion, T.S. presents to the ED with chest palpitations and light-headedness. An ECG is performed and indicates atrial fibrillation again. What decisions regarding anticoagulation need to be made?

ANTICOAGULATION FOR PAROXYSMAL, PERMANENT, OR PERSISTENT ATRIAL FIBRILLATION

Anticoagulation in valvular atrial fibrillation

Atrial fibrillation secondary to valvular heart disease has historically been recognized as a significant risk factor for stroke. Patients with atrial fibrillation who have a history of rheumatic mitral valve disease have a 17-fold higher incidence of stroke than that in matched controls. Patients with valvular atrial fibrillation require long-term, regular intensity anticoagulation with warfarin to a target INR of 2.5 (range, 2.0–3.0) to prevent thromboembolism and stroke. The landmark DOAC trials excluded patients with significant (moderate or severe) mitral stenosis and mechanical heart valves, which have been termed *valvular atrial fibrillation*. To date, DOACs have not been studied in this patient population and should be avoided at this time.[125,127]

Anticoagulation in nonvalvular atrial fibrillation

Nonvalvular heart disease is the most common cause of atrial fibrillation and, similar to valvular heart disease, represents a

significant risk of stroke in patients with atrial fibrillation. Five clinical trials have substantiated the role of warfarin in the primary prevention of systemic embolization and stroke in chronic, nonvalvular atrial fibrillation.[125,127,129] All five trials compared warfarin with a placebo and were terminated before completion because of the substantial benefit of warfarin. In comparison with a placebo, warfarin significantly reduced the risk of stroke from ~5% per year to ~2% per year, with an average relative risk reduction of 67%. Based on the results of these trials, long-term anticoagulation with warfarin to a goal INR of 2.5 (range, 2.0–3.0) is recommended in patients such as T.S., who have atrial fibrillation secondary to nonvalvular heart disease.[125,127,129]

Several clinical trials have attempted to define the comparative efficacy of warfarin versus aspirin in the prevention of stroke associated with atrial fibrillation.[125,127,130] Compared with a placebo or control, aspirin decreases the risk of stroke in patients with atrial fibrillation. However, that reduction is not as substantial as the reduction seen with warfarin. In clinical trials comparing warfarin and aspirin, the risk reduction associated with warfarin is significantly larger than that with aspirin. Subsequent trials have confirmed the superiority of warfarin over the combination of aspirin plus clopidogrel for stroke prevention in atrial fibrillation, and the increased risk of intracranial hemorrhage when aspirin and clopidogrel are combined.[131,132] As such, antiplatelet therapy (aspirin monotherapy or aspirin in combination with clopidogrel) is no longer recommended for stroke prevention in patients with atrial fibrillation. The CHA_2DS_2-VASc score is an individualized risk assessment tool endorsed by ACCP, the American Heart Association/American College of Cardiology/Heart Rhythm Society (AHA/ACC/HRS), and the European Society of Cardiology (ESC), which recommends full anticoagulation in males with a score of >1 and females ≥2[125,127,133] (see Chapter 15, Cardiac Arrhythmias).

Although oral anticoagulation is preferred for stroke prevention in patients with atrial fibrillation, percutaneous LAA occlusion has been approved as an alternative for patients deemed to be poor

candidates for long-term anticoagulation (eg, intracranial bleeding without a reversible cause). LAA occlusion with the Watchman device was noninferior to VKAs for stroke prevention in patients with atrial fibrillation and with lower bleeding rates. Following LAA occlusion with a Watchman device, aspirin 75 to 325 mg daily is initiated indefinitely, whereas warfarin (INR range; 2–3) is used for 45 days postoperatively or until adequate LAA sealing is confirmed by TEE. When warfarin is discontinued, clopidogrel is started for 6 months. The ESC Guidelines also list the use of a DOAC as a possible alternative to warfarin.[127,133] A small retrospective review has shown DOACs to be noninferior to warfarin when used post the Watchman procedure and may result in fewer adverse outcomes.[134] Patients tend to be referred for LAA occlusion when they have a high-bleeding risk. However, many patients previously thought to be poor candidates for warfarin may do well on a DOAC. Recently, a study in the Czech Republic, which included high stroke risk (mean CHA_2DS_2-VASc score of 4.7) and patients with atrial fibrillation at risk for bleeding, showed LAA occlusion was noninferior to DOACs in preventing major atrial fibrillation–related cardiovascular, neurologic, and bleeding events.[135] Similarly, a retrospective analysis of Danish registry data in patients undergoing LAA occlusion with an Amplatzer Amulet Left Atrial Appendage Occluder® device (Amplatzer Amulet Left Atrial Appendage Occluder® by Abbott Medical), was shown to have similar stroke prevention efficacy and lower bleeding when compared to those receiving stroke prevention with a DOAC.[136] Therefore, the decision to undergo LAA occlusion and specific postoperative anticoagulation must be individualized.

Direct Oral Anticoagulants

The direct thrombin inhibitor (dabigatran) and direct factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban) have all been compared to warfarin for stroke prevention in patients with nonvalvular atrial fibrillation.[137–140]

DOACs are currently recommended over warfarin as first-line therapy for stroke prevention in patients with atrial fibrillation by

ACCP and AHA/ACC/HRS and as an equivalent option to warfarin by the ESC.[125,127,133] Patient-specific characteristics such as age, renal function, weight, concomitant medications, bleeding risk, and past medical history should be considered when selecting the most appropriate anticoagulant for initial therapy. Cost, insurance coverage, and patient preference with regard to number of daily doses, frequency of monitoring, and so on must also be taken into consideration[141] (see Chapter 15, Cardiac Arrhythmias).

The decision to continue long-term anticoagulation with warfarin in T.S. should be based on an evaluation of the likelihood that her atrial fibrillation will become chronic with a paroxysmal, persistent, or permanent presentation, as well as an assessment of her risk of stroke compared with her risk of anticoagulant-associated bleeding complications. Because of her age, history of hypertension, and that she is female (CHA_2DS_2-VASc score of 3), the appropriate strategy should be long-term anticoagulation, either with full-dose DOAC therapy or warfarin at a goal INR of 2.5 (range, 2.0–3.0).

Cardiac Valve Replacement

MECHANICAL PROSTHETIC VALVES

CASE 11-10

QUESTION 1: P.B., a 59-year-old female with a history of rheumatic mitral valve disease, has undergone mitral valve replacement (MVR). A St. Jude™ (Abbott) (bileaflet mechanical) valve has been implanted, and heparin therapy is initiated postoperatively.

Does P.B. require continued anticoagulation with warfarin?

Mechanical prosthetic valves confer a significant thromboembolic risk by providing a foreign surface in contact with blood components on which platelet aggregation and thrombus formation can occur. Valvular thrombosis can impair the integrity of valve function and can lead to embolization with systemic manifestations, including stroke.[142,143] The incidence of thromboembolic complications

depends on the type of artificial valve (caged ball [Starr-Edwards, Edwards Lifesciences] > tilting disk [Medtronic-Hall, Medtronic; Björk-Shiley, Pfizer] > bileaflet [St. Jude™]), as well as the anatomic position of the replacement (dual valve replacement > mitral > aortic).[144]

Long-term anticoagulation is required in patients with mechanical valve replacement because it significantly reduces the risk of stroke and other manifestations of systemic embolization (see Table 11-9). Trials comparing different intensities of oral anticoagulation with warfarin in mechanical valve replacement helped identify the intensity of anticoagulation that protects against thromboembolic risk while reducing the incidence of hemorrhagic complications.[145] Patients with a mechanical aortic valve replacement (AVR) (St. Jude™ bileaflet or single tilting disk) in the aortic position should receive long-term anticoagulant therapy with warfarin to a target INR of 2.5 (range, 2.0–3.0).[142,143] For patients without risk factors who receive a mechanical On-X® (On-X Life Technologies) aortic heart valve, warfarin targeted to an INR of 2.5 (range, 2.0–3.0) in addition to low-dose aspirin is recommended. After the initial 3 months of therapy, the INR goal can be lowered to a range of 1.5–2.0.[143] For all other mechanical valve types in the aortic position (caged ball) or in those with additional risk factors (atrial fibrillation, previous VTE, left ventricular dysfunction, hypercoagulable state), and for any mechanical MVR, chronic warfarin therapy with a target INR of 3.0 (range, 2.5–3.5) is recommended (see Table 11-9). The concurrent use of low-dose aspirin (81 mg daily) is recommended for patients with mechanical mitral or aortic valve at low-bleeding risk.

In 2012, the Randomized, Phase II Study to Evaluate the Safety and Pharmacokinetics of Oral Dabigatran Etexilate in Patients after Heart Valve Replacement (RE-ALIGN) trial was halted early after demonstrating a significant increase in thromboembolic events such as valve thrombosis, MI, TIA, and stroke as well as a significant increase in bleeding when taking dabigatran versus warfarin in patients with mechanical prosthetic valves.[146] Based on these results as well as on case reports reporting valve thrombosis following transition from warfarin to dabigatran, the FDA issued a MedWatch

safety alert recommendation that dabigatran should not be used in any patient with a mechanical heart valve. Subsequently, dabigatran's product information was also updated to include this contraindication. Based on the results of this trial, no other DOAC has been tested in the population; thus, no DOAC should be used in patients with mechanical prosthetic valves. Therefore, P.B. would be required to continue warfarin indefinitely with a target INR of 3.0 (range, 2.5–3.5) to reduce the risk of stroke and other systemic embolism.

BIOPROSTHETIC VALVES

CASE 11-11

Question 1: E.F., an 82-year-old female with a history of symptomatic aortic stenosis, has received a bioprosthetic (mammalian) AVR.

Is anticoagulant therapy required in E.F.?

Bioprosthetic heart valves extracted from mammalian sources (porcine or bovine xenografts, homografts) are significantly less thrombogenic than are mechanical prosthetic valves. The period of greatest thromboembolic risk appears to be during the first 3 months after implantation. Therefore, anticoagulation with warfarin to an INR goal of 2.5 (range, 2.0–3.0) is recommended for 3 to 6 months following implantation of a bioprosthetic aortic or mitral valve in patients at low risk for bleeding (see Table 11-9). Alternatively, in the absence of other indications for oral anticoagulation, treatment with only aspirin 75 to 100 mg daily is also reasonable in patients with a bioprosthetic aortic or mitral valve. Regardless of whether anticoagulation is initiated, long-term aspirin therapy (75–100 mg) is recommended.[142,143] More about E.F.'s bleeding risk would need to be determined; however, because of her age, long-term aspirin therapy only may be reasonable.[143] The RIVER (*R*ivaroxaban for valvular heart disease and atrial fibrillation) trial was designed to assess the efficacy and safety of rivaroxaban compared with warfarin in those patients with atrial fibrillation receiving a

bioprosthetic mitral valve. The majority of patients were randomized >3 months after receiving the mitral valve implantation. Rivaroxaban was shown to be noninferior to warfarin with respect to mean time until the occurrence of major clinical events (death, major cardiovascular events, or major bleeding at 12 months).[147] The 2017 ESC Guidelines recommend VKA therapy when long-term anticoagulation therapy is needed in patients with a bioprosthetic valve. However, they also suggest that a DOAC may be used in patients with atrial fibrillation associated with a bioprosthesis after the third postoperative month.[148] The 2020 ACC/AHA Guidelines state that the decision to choose warfarin or a DOAC for patients with atrial fibrillation and a bioprosthetic valve should be made in a shared decision-making process based on the CHA_2DS_2-VASc score.[143]

Transcatheter aortic valve implantation (TAVI) is a new technique that avoids the open chest approach. The 2020 AHA/ACC Guidelines recommend lifelong aspirin (75–100 mg daily) with either clopidogrel 75 mg daily for the first 3 to 6 months or warfarin with a goal INR of 2.5 (range, 2.0–3.0) for the first 3 months following surgery in low-bleed risk patients.[143] The GALILEO (*G*lobal study comparing a rivaroxaban-based antithrombotic strategy to an antiplatelet-based strategy after transcatheter aortic valve replacement to *O*ptimize clinical outcomes) trial compared low-dose rivaroxaban (10 mg daily) plus low-dose aspirin (75–100 mg daily) to low-dose aspirin plus clopidogrel (75 mg daily). This trial was terminated prematurely because the rivaroxaban strategy was associated with a higher risk of death or thromboembolic complications and a higher risk of bleeding than with those in the antiplatelet-based strategy.[149] Therefore, in the absence of other indications for oral anticoagulation, this regimen is contraindicated following TAVI.[143] The POPular TAVI trial randomized patients already receiving anticoagulation with a VKA or DOAC to receive either clopidogrel or no clopidogrel for 3 months following TAVI. Patients receiving anticoagulation alone had a lower incidence of

serious bleeding over 1 year than those receiving anticoagulation plus clopidogrel.[150]

BRIDGE THERAPY

Management of Anticoagulation Around Invasive Procedures

CASE 11-12

QUESTION 1: L.P. is a 48-year-old female with a history of valvular heart disease and a St. Jude™ MVR. She is adequately anticoagulated with warfarin 7.5 mg once daily to a goal INR range of 2.5 to 3.5. Recently, she has reported episodic rectal bleeding and is scheduled for a colonoscopy in several weeks. Her gastroenterologist calls the anticoagulation clinic to determine the most appropriate plan for reversal of her warfarin before the procedure.

What are the periprocedural options?

When an invasive procedure is planned, it is often necessary to reverse the effects of warfarin to minimize the risk of bleeding complications associated with the procedure, which can be worsened by the presence of an anticoagulant. It can take several days for the anticoagulant effect of warfarin to be reversed after discontinuation of the drug, but in that period of time, a patient may be at risk for thromboembolic complications associated with underanticoagulation. *Bridge therapy* is the term that refers to the use of a relatively short-acting injectable anticoagulant (UFH, LMWH) as a substitute for warfarin before and immediately after an invasive procedure to shorten the period of time a patient is without any anticoagulation.[143,151] Because UFH and LMWH have shorter elimination half-lives than does warfarin, they can be stopped just before the invasive procedure without increasing the risk of bleeding associated with the procedure. The last dose of LMWH and SC UFH should be given at least 24 hours before the scheduled procedure,

whereas IV UFH infusions are discontinued 6 hours before the procedure. The timing of the last dose of LMWH may need to be extended based on a patient's renal function because it is renally eliminated. Because of their faster onsets of effect, these agents are resumed after invasive procedures once hemostasis is achieved to establish an immediate degree of anticoagulation. Resumption of therapeutic injectable anticoagulants after a high-bleeding risk surgery should be delayed until at least 48 to 72 hours postoperatively, whereas patients undergoing lower bleeding risk procedures can be restarted 24 hours later. Warfarin is resumed simultaneously, and the bridging anticoagulant is continued until the INR reaches the therapeutic range.[143,151]

Current bridging recommendations are based on clinical trials as well as on results from case series, observational studies, and nonrandomized trials involving patients with various indications for anticoagulation, including valve replacement. The decision to use bridging depends on the risk of bleeding associated with continued anticoagulation for the surgery or procedure to be performed and on the risk of thromboembolism associated with underanticoagulation in the patient in question. A large registry called the Outcomes Registry for Better Informed Treatment of Atrial Fibrillation (ORBIT-AF) included patients with atrial fibrillation who underwent temporary interruption of oral anticoagulation therapy and showed that bridging was associated with higher risk of bleeding and adverse events.[152] Shortly after, the results of the BRIDGE (Bridging anticoagulation in patients who require temporary interruption of warfarin therapy for an elective invasive procedure or surgery) trial that randomized patients with atrial fibrillation to receive bridging therapy with LMWH or placebo showed findings similar to that of the ORBIT-AF registry. The study showed no difference in the rate of arterial thromboembolism between the bridging and nonbridging group; however, the bridging group showed significantly higher rates of major bleeding. The mean $CHADS_2$ score was 2.3 and patients with mechanical heart valve or stroke, systemic embolism, and TIA within the previous 12 weeks were excluded from the trial. Major surgical

procedures associated with high rates of arterial thromboembolism and bleeding were also underrepresented. Therefore, the results from the BRIDGE trial should not be applied to patients who were underrepresented.[153] Individualized risk assessment and bridge therapy planning are necessary for each patient who may require temporary discontinuation of warfarin. Recommendations for risk stratification are outlined in **Table 11-23**. In 2017, the ACC published a consensus decision pathway regarding the periprocedural management of anticoagulation in patients with nonvalvular atrial fibrillation. High-risk patients with a CHA_2DS_2VASc score of 7 to 9 or ischemic stroke, TIA, or systemic embolism within the previous 3 months should likely receive parenteral anticoagulation bridging if warfarin requires interruption. Those at low risk for thromboembolism with a CHA_2DS_2VASc score of <4 or without previous ischemic stroke, TIA, or systemic embolism do not require parenteral bridging if warfarin interruption is required. Patients at moderate risk with a CHA_2DS_2VASc score of 5 or 6 or those with a previous ischemic stroke, TIA, or systemic embolism >3 months prior require further evaluation of patient's individualized bleeding risk. If patients have a high-bleeding risk, bridging therapy is not recommended. However, if patients have a low-bleeding risk, bridging should be considered in those with a history of ischemic stroke, TIA, or systemic embolism.[154] The ACC/AHA also include recommendations regarding bridge therapy in patients with valvular disease in the latest 2020 guidelines. Here, parenteral anticoagulation bridge therapy is recommended in those with mechanical MVR, mechanical AVR with any thromboembolic risk factor, or an older generation AVR unless the bleeding risk outweighs the thromboembolic risk.[143] The bleeding risk of a performed procedure or surgery must also be weighed. Efforts should be made to continue oral anticoagulation in a patient with high thromboembolic risk undergoing a procedure with low-bleeding risk, such as a dental extraction or cataract surgery. **Table 11-24** includes examples of high- versus low-bleeding risk surgeries.

Table 11-23
Risk Stratification for Determining the Need for Bridge Therapy

	Indication for VKA Therapy		
Risk Stratum	**Mechanical Heart Valve**	**Atrial Fibrillation**	**Venous Thromboembolism**
High	■ Any mitral valve prosthesis ■ Older (caged ball) aortic valve prosthesis ■ Recent (within 6 months) stroke or transient ischemic attack	■ $CHADS_2$-VASc score of >7, recent (within 3 months) stroke or transient ischemic attack ■ Rheumatic valvular heart disease	■ Recent (within 3 months) VTE ■ Severe thrombophilia (eg, deficiency of protein C, protein S, or antithrombin, antiphospholipid antibodies, or multiple abnormalities)
Moderate	■ Bileaflet aortic valve prosthesis and one of the following: atrial fibrillation, prior stroke or transient ischemic attack, hypertension, diabetes, congestive heart failure, age >75 years	■ $CHADS_2$-VASc score of 5–6 or prior stroke or transient ischemic attack > 3 months previously	■ VTE within the past 3–12 months (consider VTE prophylaxis rather than full intensity bridge therapy) ■ Nonsevere thrombophilic conditions (eg, heterozygous factor V Leiden mutation, heterozygous factor II mutation) ■ Recurrent VTE ■ Active cancer (treated within 6 months or palliative)
Low	■ Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	■ $CHADS_2$-VASc score of 1–4 (no prior stroke or transient ischemic attack)	■ Single VTE occurred >12 months ago and no other risk factors

CHADS2-VASc score, congestive heart failure: 1 pt; hypertension: 1 pt; age: ≥75 years 2 pts; diabetes mellitus: 1 pt; prior stroke or TIA or thromboembolism: 2 pts; vascular disease: 1 pt; age: 65 – 74 years 1 pt; sex category: 1 pt female; VKA, vitamin K antagonist; VTE, venous thromboembolism.

Table 11-24
Bleed Risk of Selected Procedures

Minimal Bleeding Risk	**Low-Bleeding Risk (2-day risk of major bleed <2%)**	**High-Bleeding Risk (2-day risk of major bleed >2%)**
Minor dermatologic procedures (eg, excision of basal and squamous skin cancers, actinic keratosis, and premalignant or cancerous skin nevi)	Minor dental procedures (eg, simple dental extractions, restorations, prosthetics, endodontics)	Cancer surgery
Cataract procedures	Cutaneous/lymph node biopsies	Major orthopedic surgery

Dental cleanings, fillings	Shoulder/foot/hand surgery	Reconstructive plastic surgery
	Coronary angiography	Transurethral prostate resection, bladder resection, or tumor ablation
	Gastrointestinal endoscopy +/− biopsy	Nephrectomy, kidney biopsy
	Colonoscopy +/− biopsy	Colonic polyp resection
	Abdominal hysterectomy	Bowel resection
	Hemorrhoidal surgery	PEG placement, ERCP
	Bronchoscopy +/− biopsy	Cardiac, intracranial, or spinal surgery
	Epidural injections with INR <1.2	Surgery in high vascular organs (kidneys, liver, spleen)
	Pacemaker battery change	Any major operation (procedure duration >45 minutes)
	Arthroscopy	Pacemaker or cardioverter-defibrillator device implantation

For other surgeries and bleed risk, see http://jaccjacc.acc.org/Clinical_Document/PMAC_Online_Appendix.pdf

ERCP, endoscopic retrograde cholangiopancreatography; INR, international normalized ratio; PEG, percutaneous endoscopic gastrostomy.

Source: Warfarin Use in Adults: Clinical Care Guideline, University of Illinois Hospital and Health Sciences System.

Clinical outcomes in patients bridged with LMWH or UFH are similar and overall costs are lower for LMWH because of the avoidance of hospital admission for IV UFH administration; therefore, the use of LMWH is recommended whenever possible.[151] UFH may be preferred in patients with significant renal impairment (CrCl <30 mL/minute), or if LMWHs are used, reduced doses are suggested.[10] Monitoring anti-Xa levels for accumulation may be prudent if patients require a prolonged course of therapy (over 7 days). A sample plan for bridge therapy based on the risk of thromboembolism and on renal function is presented in **Table 11-25**.

Table 11-25
Sample LMWH Bridging Plan

	Action		
Day	**Warfarin**	**LMWH**	**Laboratories**
−6	Last warfarin dose	N/A	INR; skip dose if supratherapeutic.
−5	No warfarin	N/A	
−4	No warfarin	Start LMWH	
−3	No warfarin	LMWH	
−2 to −1	No warfarin	LMWH; last dose 24–36 hours before procedure	
0–day of procedure	Resume warfarin at usual dose if hemostasis is achieved.[a]	No LMWH	Ensure INR is appropriate for surgery.[b] CBC
1	Resume warfarin if not started the day prior.	LMWH; resume following minor surgery No LMWH following major surgery	
2–3	Warfarin	LMWH; resume following major surgery if bleeding controlled	
4	Warfarin	LMWH	
5–7	Warfarin	LMWH	INR; discontinue when therapeutic Consider CBC, CrCl, anti-Xa level with continued need for LMWH.

CBC, complete blood count; CrCl, creatinine clearance; INR, international normalized ratio; LMWH, low-molecular-weight heparin.

[a]Consider giving 1.5 times the usual warfarin dose for first 2 days when warfarin is reinitiated.

[b]INR <1.5 required for most surgical procedures.

Because L.P. has a mechanical MVR, her risk of thromboembolism associated with underanticoagulation is

considered high. Therefore, she should receive bridge therapy with an injectable anticoagulant while warfarin is held. Her renal function is normal, and her health care insurance covers injectable drugs. Therefore, her plan will include early discontinuation of warfarin 5 days before the procedure and substitution with enoxaparin 1 mg/kg every 12 hours when the INR falls below the lower limit of the therapeutic range. The last dose of enoxaparin should be given 24 hours before the procedure to minimize the risk of bleeding at the time of the procedure. After the procedure, warfarin should be restarted at her usual dose, and enoxaparin should be continued until the INR is >2.5, the lower limit of L.P.'s therapeutic range. For indications other than mechanical valves, enoxaparin 1.5 mg/kg every 24 hours may be used as an alternative to avoid twice-daily injections.

The relatively short half-lives of DOACs allow for a reduced duration of underanticoagulation when therapeutic interruption is required. Patients receiving DOAC therapy do not require bridge therapy with parenteral anticoagulants because the half-lives are similar. Preoperative discontinuation of a DOAC is based on a patient's individual renal function, so this must be assessed before providing perioperative recommendations. Similar to LMWH, DOACs can be restarted on the day following the procedure assuming hemostasis has been achieved. Following high-bleed risk procedures, it is reasonable to wait 48 to 72 hours before resuming the DOAC.[154] This was confirmed with the Perioperative Anticoagulation Use for Surgery Evaluation (PAUSE) trial. This cohort study evaluated rates of major bleeding and arterial thromboembolism in patients taking dabigatran, rivaroxaban, or apixaban for atrial fibrillation who were scheduled for an elective procedure. DOAC regimens were stopped 1 to 2 days before a low- or high-bleed risk procedure, respectively, and resumed 1 day after a low-bleed risk procedure and 2 to 3 days following a high-bleed risk procedure. Edoxaban was not evaluated because it was not yet approved at the time of enrollment. After 30 postoperative days, patients with atrial fibrillation who had DOAC therapy interrupted for elective surgery or procedure without heparin bridging or

measurement of coagulation function was associated with low rates of major bleeding and arterial thromboembolism.[155] **Table 11-26** summarizes recommendations for perioperative DOAC interruption.

Table 11-26

Perioperative Recommendations for Interruption of Direct Oral Anticoagulants

Drug	Renal Function CrCl (mL/minute)	Low-Bleed Risk Surgery	High-Bleed Risk Surgery	Resumption of Therapy: Low-Bleed Risk Surgery[a]	Resumption of Therapy: High-Bleed Risk Surgery[a]
Dabigatran	CrCl >50	1–2 days before	3 days before	1 day after[b]	2–3 days after[b]
	CrCl 30–50	3 days before	3–4 days before		
	CrCl <30	3 days before	5–6 days before		
Rivaroxaban	CrCl >50	1–2 days before	1–3 days before	1 day after[b]	2–3 days after[b]
	CrCl 30–50	2 days before	2–3 days before		
	CrCl 15–29.9	3 days before	2–3 days before		
Apixaban	CrCl >50	1–2 days before	2–3 days before	1 day after[b]	2–3 days after[b]
	CrCl 30–50	2–3 days before	2–3 days before		
Edoxaban	CrCl >15	1–2 days before	2–3 days before	1 day after[b]	2–3 days after[b]
	Discontinue edoxaban at least 24 hours before invasive or surgical procedures				

CrCl, creatinine clearance; DOAC, direct oral anticoagulant.

[a]Ensure adequate hemostasis is achieved before resuming anticoagulation.

[b]When initiating a direct oral anticoagulant (DOAC) after an orthopedic procedure for venous thromboembolism (VTE) prophylaxis, anticoagulant should be taken 12 to 24 hours after surgery once hemostasis has been established.

DRUG INTERACTIONS

Interactions With Prescription Drugs

CASE 11-13

QUESTION 1: P.T., a 48-year-old female, received a mechanical mitral valve prosthesis 5 years ago and has been anticoagulated with warfarin 6 mg/day

with good control. She asks to see you today in your anticoagulation clinic. After returning from an urgent appointment with her primary care physician for treatment of a skin infection that yielded a positive test result for community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) and was given a prescription for trimethoprim–sulfamethoxazole (TMP-SMX) twice a day for 10 days today. She is allergic to penicillin and has gastric intolerance to tetracycline.

How will the combination of warfarin and TMP-SMX affect P.T.'s anticoagulation control? Should her warfarin dosage be adjusted or another drug substituted for TMP-SMX?

Drug interactions with warfarin occur by a number of different mechanisms and can have a significant impact on the anticoagulant effect of warfarin.[156,157] Elevations or reductions in INR have been observed when interacting drugs are added to or discontinued from the medication regimens of patients taking warfarin or when used intermittently. Clinically significant hemorrhagic or thromboembolic complications can result. Careful selection of both prescription and nonprescription medications, appropriate INR monitoring, and detailed patient education regarding drug interactions are important interventions for pharmacists caring for patients taking warfarin. A selection of the hundreds of drugs that have been reported to interact with warfarin, including mechanisms of interaction and effect on INR, is provided in **Table 11-27**. Further information regarding the management of drug interactions can be found in Chapter 3, Drug Interactions.

Table 11-27
Warfarin Drug Interactions

Target	Effect	Response		Examples (Not Inclusive)		
Clotting factors	Increased synthesis	Decreased INR	Vitamin K			
	Decreased synthesis	Increased INR	Broad-spectrum antibiotics			
	Increased catabolism	Increased INR	Thyroid hormones			
	Decreased catabolism	Decreased INR		Methimazole		Propylthiouracil
Warfarin metabolism	Inhibition	Increased INR	Acetaminophen	Allopurinol	Amiodarone	Azole antifungals
			Cimetidine	Fluoroquinolones	Macrolides	Metronidazole
			Propafenone	SSRIs	Statins	Sulfa antibiotics
	Induction	Decreased INR	Barbiturates	Carbamazepine	Doxycycline	Griseofulvin
Nafcillin		Phenytoin	Primidone	Rifampin		
Hemostasis	Additive antithrombotic effects	Increased bleeding risk	Aspirin	NSAIDs	Salicylates	GPIIb/IIIa inhibitors
	Additive antico-agulant response	Increased bleeding risk	Heparin	LMWH	Direct thrombin inhibitors	Thrombolytics
		Decreased INR	Cholestyramine	Colestipol	Sucralfate	
Absorption	Reduced	Decreased INR	Ascorbic acid	Azathioprine	Corticosteroids	Cyclosporine
Unknown		Increased INR	Androgens	Fenofibrate	Cyclophosphamide	Gemfibrozil

GP, glycoprotein; INR, international normalized ratio; LMWH, low-molecular-weight heparin; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

Although warfarin is highly bound to protein (primarily to albumin), and can be displaced from protein-binding sites by a number of weakly acidic drugs, these interactions typically do not result in clinically significant elevations in PT/INR.[158] Warfarin displaced from protein-binding sites is readily available for elimination by hepatic metabolism, resulting in increased clearance without a significant change in the free-drug concentration.

Other types of interactions with warfarin are much more significant. Pharmacodynamic interactions are those that alter the physiology of hemostasis, particularly interactions that influence the synthesis or degradation of clotting factors or that increase the risk of bleeding through inhibition of platelet aggregation. Pharmacokinetic interactions influence the absorption and metabolism of warfarin, and many clinically significant interactions with warfarin occur when warfarin metabolism is induced or inhibited. Interactions involving agents known to influence the hepatic microsomal enzyme systems responsible for the metabolism of the more potent S(−)-warfarin

(CYP2C9) are more significant than are those that influence the enzymes that metabolize R(+)-warfarin (CYP1A2, CYP3A4).

Sulfamethoxazole can increase the effect of warfarin significantly by stereoselectively inhibiting the metabolism of the more potent S(−)-enantiomer of warfarin. Potentiation of warfarin activity after inhibition of metabolism usually takes several days, and the effect may be slow to resolve once the offending agent is discontinued. In addition, fever associated with the infection for which TMP-SMX has been prescribed may enhance the catabolism of vitamin K–dependent clotting factors, resulting in an accentuated hypoprothrombinemic response. This effect will dissipate as the fever abates with antibiotic therapy.

For P.T., the ideal choice would be to discontinue TMP-SMX and use a noninteracting alternative. The decision of which agent to use must consider both the treatment(s) of choice for the clinical indication along with patient factors such as reported allergies or intolerances. In P.T.'s case, she has a penicillin allergy and intolerance to tetracyclines, both of which would prevent their use. If a noninteracting alternative is not clinically appropriate, the concomitant use of an interacting agent is not absolutely contraindicated in patients taking warfarin. Use of TMP-SMX in P.T. would be acceptable if she is monitored frequently and carefully, with adjustment of warfarin dosages as necessary to maintain her INR within the therapeutic INR range of 2.5 to 3.5 and with attention to potential hemorrhagic complications. No initial change in the dosage of warfarin should be made because it may take several days for the interaction to become apparent. The INR should be repeated within 3 days, with warfarin dosing adjustments and subsequent monitoring guided by initial INR results.

CASE 11-14

QUESTION 1: G.H. is a 54-year-old male on long-term anticoagulation for multiple, bilateral DVTs, most recently 1 year ago, for which he takes warfarin 7.5 mg daily. He had a knee replacement surgery 6 months ago and had a complication of infected hardware, for which he needs to start IV rifampin in a skilled nursing facility for several weeks. His orthopedic physician is asking

about whether G.H. can be switched to an alternate anticoagulant because he knows that there is a drug interaction with warfarin and rifampin.

What options are available to him?

Although the DOACs are less prone to drug interactions than is warfarin, all of them are P-gp substrates and can have their concentrations reduced by rifampin, which is a strong P-gp inducer.[159] At this time, dabigatran, rivaroxaban, apixaban, and edoxaban are all contraindicated with rifampin per package labeling and are not suitable options for G.H. Drug interactions for DOACs are summarized in Table 11-6.

The interaction with warfarin and rifampin can be significant, with a potentially large dose increase (sometimes up to three times the original dose) of warfarin necessary to maintain G.H. in the therapeutic range. If G.H. is in a facility where his INRs can be measured frequently, such as every few days, it may be appropriate to maintain him on warfarin while continuing the rifampin, until the degree of the interaction can be detected, and a new stable dose can be determined. Alternatively, if G.H. is receiving the antibiotics at home, it may be appropriate for him to acquire a home INR meter and perform warfarin self-testing of his INRs. It has been shown that individuals performing patient self-testing (almost all testing weekly) had better time in therapeutic range (TTR) than did those who underwent in-clinic testing every 4 weeks using high-reduced anticoagulation management.[160] A substudy of this trial also showed that individuals on chronic anticoagulation who perform self-testing more often (ie, weekly or twice weekly) had a modestly higher TTR compared to monthly testing.[161] The costs of the self-testing meter and supplies are often covered by the patient's insurance; however, sometimes the poor reimbursement for managing anticoagulation services this way can limit providers' willingness to offer patient-self testing. If reimbursement is not a concern (such as in a closed insurance system), then patient self-testing can be a way to empower patients to take more control of their warfarin management and reduce the burden of INR monitoring.

LMWH, UFH, and fondaparinux are also reasonable options for G.H. to use, especially if his INRs cannot be stabilized while receiving the rifampin. However, again, there could be barriers to self-injection and insurance limitations that may make it difficult to continue these agents for a prolonged length of time.

Case 11-14, Question 2: Can G.H. return to using his ibuprofen for pain control?

This question illustrates one of the most difficult therapeutic dilemmas for a patient taking warfarin. All NSAIDs have the potential to cause gastric irritation by inhibiting cytoprotective prostaglandins, thereby providing a focus for GI bleeding. In addition, most NSAIDs inhibit platelet aggregation, which compromises effective clotting and can lead to bleeding complications.[162]

These effects can increase the risk of hemorrhagic complications significantly in patients taking warfarin who are prescribed concurrent NSAID therapy. In a retrospective cohort study of patients ages 65 years and older, the risk of hospitalization for bleeding peptic ulcer disease was approximately three times higher for patients taking concurrent warfarin and an NSAID versus those taking either drug alone, and almost 13 times higher than in patients taking neither warfarin nor an NSAID.[163] Warfarin therapy is considered a relative contraindication to NSAID use.

In patients such as G.H., routine use of NSAIDs with long-term anticoagulation should be avoided. Any patients requiring combined warfarin and NSAID therapy for limited periods of time should be followed up closely and observed routinely for signs and symptoms of bleeding, with frequent stool testing for GI bleeding. Patients should be counseled to avoid additional NSAID use whenever possible, including use of aspirin, and to seek assistance from a pharmacist to prevent inadvertent NSAID use when selecting over-the-counter (OTC) medications, because some OTC cold preparations contain NSAIDs, aspirin, or aspirin-related compounds.

The analgesic and antipyretic of choice in patients taking warfarin is acetaminophen, which has not been consistently shown to increase the risk of bleeding. At doses >2 g/day, acetaminophen can enhance the anticoagulant effect of warfarin.[164] It has been suspected of directly inhibiting CYP2C9 and CYP1A2, and toxic metabolites of acetaminophen have been suspected of inhibiting hepatic enzymes as well. Nevertheless, it can be used safely when used occasionally, and even when used routinely. INR monitoring is sufficient to detect any potential interaction. Other pain-relieving options to be considered that do not increase the bleeding risk include tramadol, gabapentin, pregabalin, topical lidocaine patches, and opiates.

Chronic Stable Angina

Angela M. Thompson and Toby C. Trujillo

CORE PRINCIPLES		CHAPTER CASES
CHRONIC STABLE ANGINA—MEDICAL MANAGEMENT		
1	Chronic stable angina is a clinical syndrome resulting from an imbalance in myocardial oxygen supply and demand. The supply–demand imbalance is typically a result of coronary atherosclerosis.	**Case 12-1 (Questions 1–3)**
2	The modification of cardiovascular disease (CVD) risk factors and adoption of healthy lifestyles is a key strategy in both the primary prevention of coronary artery disease (CAD) and slowing the progression of established CAD.	**Case 12-1 (Questions 7–9)** **Case 12-2 (Question 2)**
3	Standard therapy for all patients with chronic stable angina includes sublingual nitroglycerin, antiplatelet	**Case 12-1 (Questions 10–14, 16)** **Case 12-3 (Question 2)**

	therapy, and an anti-ischemic agent that either restores the appropriate balance of myocardial oxygen supply and demand (β-blockers, calcium channel blockers, and long-acting nitrates) or interrupts the negative consequences of myocardial ischemia on myocardial energy consumption (ranolazine).	
4	β-Blockers are the preferred initial agents for prevention of ischemic symptoms, especially in patients who have a history of myocardial infarction (MI) or heart failure.	**Case 12-1 (Questions 11–13, 15)**
5	Although effective as monotherapy, long-acting calcium channel blockers are typically added on to β-blocker therapy if additional control of ischemic symptoms is needed.	**Case 12-2 (Question 1)**
6	Long-acting nitrates should never be used as monotherapy but can be used as add-on therapy to other anti-ischemic options in chronic stable angina.	**Case 12-1 (Questions 16–19)**
7	Although ranolazine can be used as initial therapy for chronic stable angina, it is typically reserved as a second-line option. It is especially useful in patients who cannot tolerate further decreases in heart rate and blood pressure secondary to the use of traditional antianginal agents.	**Case 12-2 (Questions 3, 4)**
CHRONIC STABLE ANGINA—REVASCULARIZATION		

1	Myocardial revascularization can be accomplished either through percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG). In most patients, both are equally effective in reducing myocardial ischemia.	**Case 12-1 (Question 4)** **Case 12-4 (Question 3)**
2	Certain patients who are at high risk for morbidity and mortality from CAD derive a mortality benefit with CABG as compared to PCI or medical management.	**Case 12-3 (Question 1)** **Case 12-4 (Question 3)**
3	In patients not at high risk, optimal medical management is as good as PCI in the long-term management of chronic stable angina, including the prevention of MI and death.	**Case 12-1 (Question 6)**
4	Patients who undergo myocardial revascularization either with PCI or CABG should still receive optimal pharmacotherapy for chronic stable angina.	**Case 12-4 (Question 3)**
5	Appropriate pharmacotherapy for patients undergoing elective PCI plus myocardial stent implantation should include dual antiplatelet therapy with aspirin and a $P2Y_{12}$ antagonist, in most cases clopidogrel therapy, for a minimum of 1 month (bare-metal stent) and ideally up to 1 year (bare-metal and drug-eluting stents).	**Case 12-1 (Question 5)** **Case 12-4 (Question 1, 2)**
6	Antiplatelet nonresponsiveness has	**Case 12-4 (Question**

	been demonstrated to be associated with an increased risk for cardiovascular events such as MI and death. An understanding of various testing modalities for antiplatelet response as well as potential drug–drug interactions that may lead to reduced antiplatelet activity will facilitate optimal pharmacotherapy in each patient.	**4, 5)**
PRINZMETAL ANGINA/CARDIAC SYNDROME X		
1	Patients with Prinzmetal angina and cardiac syndrome X typically present with severe chest pain despite having coronary arteries that are free from atherosclerosis.	**Case 12-5 (Question 1)**
2	Vasodilators are the primary mode of therapy for patients with Prinzmetal angina, whereas standard anti-ischemic options should be used for cardiac syndrome X.	**Case 12-5 (Question 2, 3)** **Case 12-6 (Question 1)**

INTRODUCTION

Coronary heart disease (CHD) includes heart failure (HF), arrhythmias, sudden cardiac death, and ischemic heart disease (IHD) such as myocardial infarction (MI) as well as unstable and stable angina pectoris. Because angina is a marker for underlying heart disease, its management is of great importance. Typical angina pectoris is characterized by substernal chest, jaw, shoulder, back, or arm pain triggered by exertion or stress, and it is relieved by rest or nitroglycerin (NTG); however, its presentation is variable.[1,2]

Patients who have a reproducible pattern of angina associated with a certain level of physical activity have chronic stable angina or exertional angina. In contrast, patients with unstable angina experience angina that is prolonged, occurs at rest, or at an increased intensity or frequency.[3] Angina often reflects underlying atherosclerotic narrowing of coronary arteries on coronary angiography. In contrast, Prinzmetal variant or vasospastic angina is associated with normal findings on coronary angiography and is thought to be caused by a spasm of the coronary artery that decreases myocardial blood flow. The presence of atherosclerosis also may lead to impairment of the normal vasodilatory function of the coronary arteries. As such, patients with coronary artery disease (CAD) who experience ischemia produced by an increase in myocardial oxygen demand (increased exertion) may also experience vasospasm at the site of atherosclerosis, further worsening the ischemic state. As such, patients with CAD likely experience angina because of both increased demand (exertion) and decreased supply (vasospasm), a phenomenon known as microvascular angina.[3]

Silent (asymptomatic) myocardial ischemia can result in transient changes in myocardial perfusion, function, or electrical activity and is detected on an electrocardiogram (ECG).[3] The patient, however, does not experience chest pain or other signs of angina during these episodes.

Epidemiology

It is estimated that 121.5 million adults in the United States have cardiovascular disease (CVD),[4] and 18.2 million of these adults have CHD.[4] Chronic stable angina is the first clinical sign of CHD in ~50% of patients.[1] Current estimates indicate 9.4 million American adults have angina pectoris, although the prevalence of angina is likely underestimated because of limited population-based data and because it is often unrecognized in patients.[4]

CVD is responsible for 17.8 million deaths worldwide and is the leading cause of death in the United States.[4] Although CHD is the leading cause of CVD death in the United States, individual mortality varies according to the patient's age, sex, cardiovascular risk profile, myocardial contractility, coronary anatomy, and specific anginal syndrome.[4]

In addition to the high morbidity and mortality associated with CHD, the economic cost to the U.S. health care system is substantial. Total direct and indirect costs associated with CHD were estimated to be $218.7 billion from 2014 to 2015.[4]

Pathophysiology

A brief review of coronary anatomy will facilitate a thorough understanding of the pathophysiology of chronic stable angina. **Figure 12-1** illustrates the normal distribution of the major coronary arteries, although variation is common between individuals.

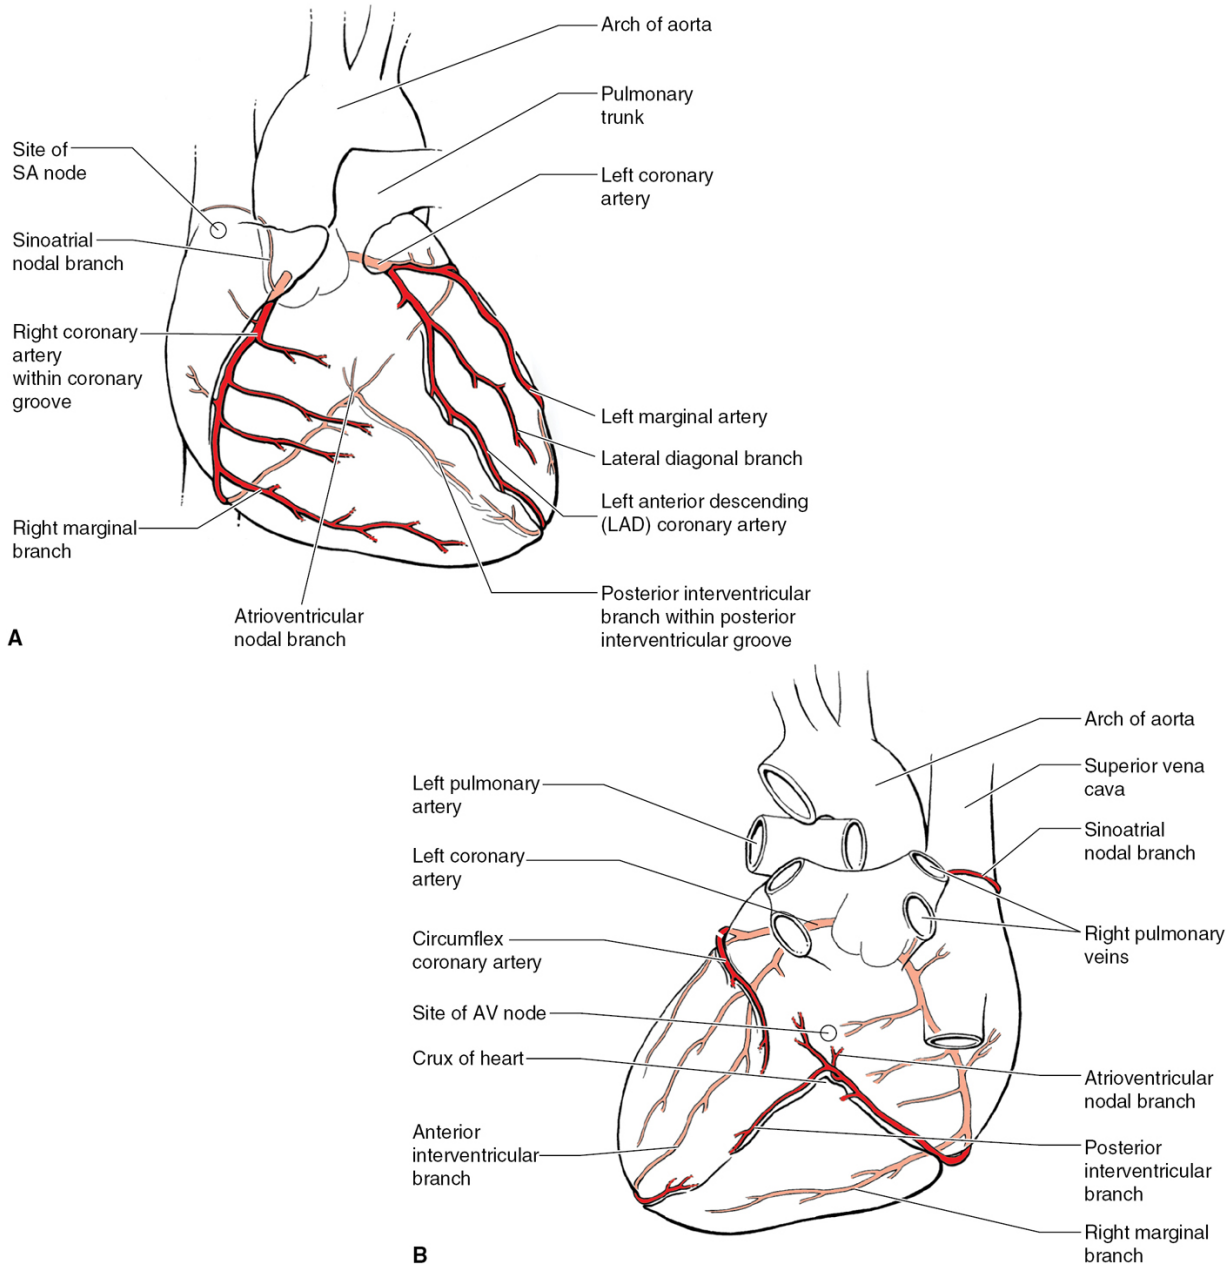

Figure 12-1 Coronary arteries. The right coronary artery (RCA) originates from the aorta and courses in the atrioventricular (coronary) groove to reach the posterior surface of the heart. The left coronary artery splits into the circumflex branch that supplies blood to the lateral and posterior walls of the left ventricle and a left anterior descending (LAD) branch that supplies blood to the anterior wall of the left ventricle. A, Anterior view. B, Posteroinferior view.

Angina pectoris typically occurs from myocardial ischemia. Ischemia in the myocardium develops when there is a mismatch between myocardial oxygen supply and demand. The underlying pathologic condition of this mismatch invariably is the presence of atherosclerosis in one or more of the coronary arteries.[3]

MYOCARDIAL OXYGEN SUPPLY AND DEMAND

The oxygen demand of the heart is determined by its workload. The major determinants of myocardial oxygen consumption are heart rate, contractility, and intramyocardial wall tension during systole (**Fig. 12-2**).[3,5] Intramyocardial wall tension, the force the heart is required to develop and sustain during contraction, is affected primarily by changes in ventricular pressures and volume. Both enlargement of the ventricle and increased pressure within the ventricle increase the systolic wall force and consequently myocardial oxygen demand. Increases in contractility and heart rate also increase oxygen demand.[6] Pharmacologic control of angina is directed toward decreasing the myocardial oxygen demand by decreasing heart rate, myocardial contractility, or ventricular volume and pressures.[3,5]

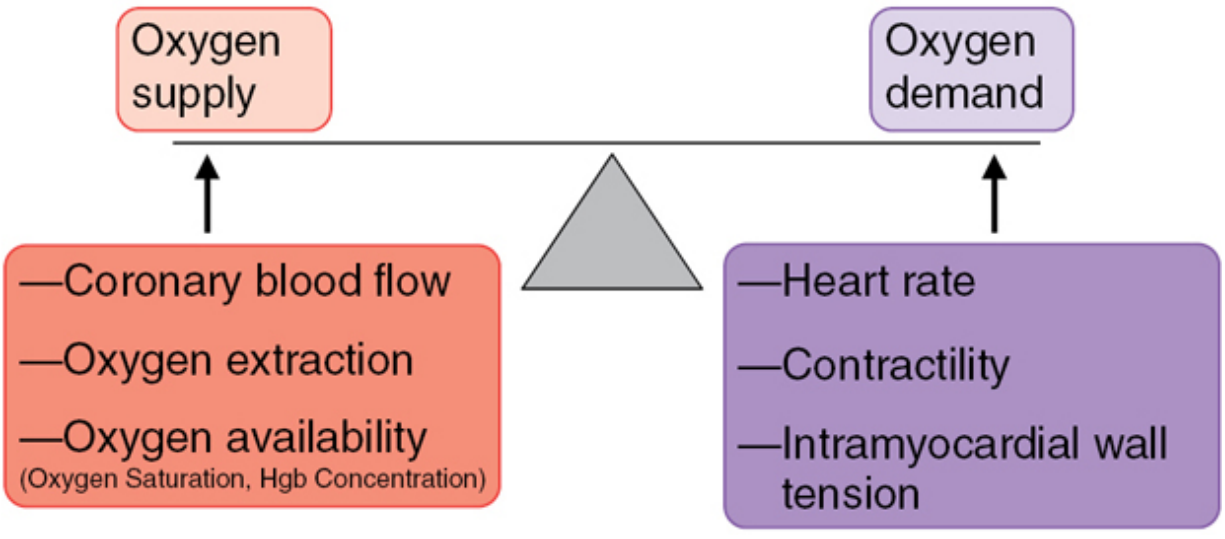

Figure 12-2 Determinants of myocardial oxygen supply and demand.

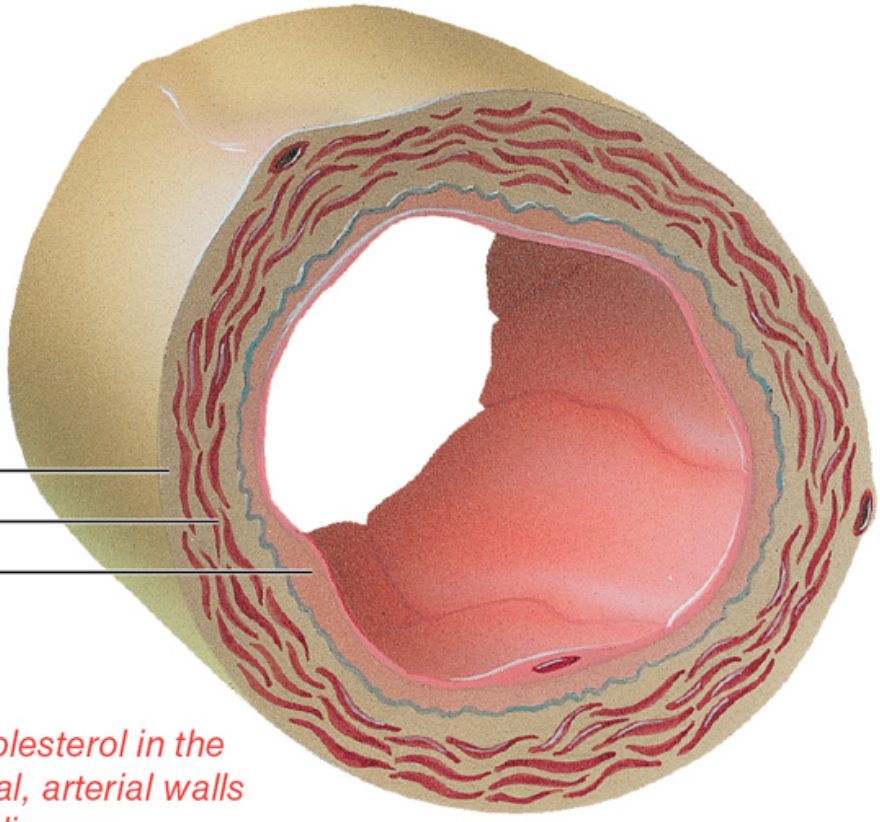
Oxygen supply to the heart is impacted by many factors, including coronary blood flow and oxygen extraction (see Fig. 12-2). Oxygen extraction by heart cells is high (~70%–75%) even at rest. When extra demand is placed on the heart, myocardial oxygen extraction increases slightly and plateaus at ~80%. Because oxygen extraction is increased only modestly when the heart is stressed, high oxygen demands must be met by increases in coronary blood flow.[7] The oxygen content of arterial blood also is important. Therefore, the hematocrit (Hct), hemoglobin (Hgb), and arterial blood gases should be monitored. In a similar fashion to targeting determinants of myocardial oxygen demand, pharmacologic control of angina is directed at improving oxygen supply through vasodilation of the epicardial coronary arteries.[5]

ATHEROSCLEROTIC VASCULAR DISEASE

Although understanding the determinants of myocardial oxygen supply and demand is important in treating CHD, of equal importance is understanding how atherosclerotic plaques develop because the underlying pathologic condition of this mismatch invariably is the presence of atherosclerosis in one or more of the coronary arteries. Understanding how the process of atherosclerosis unfolds, as well as the primary pharmacologic and nonpharmacologic interventions that help prevent progression of atherosclerosis, is an important piece in treating a patient with chronic stable angina (**Fig. 12-3**) (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).

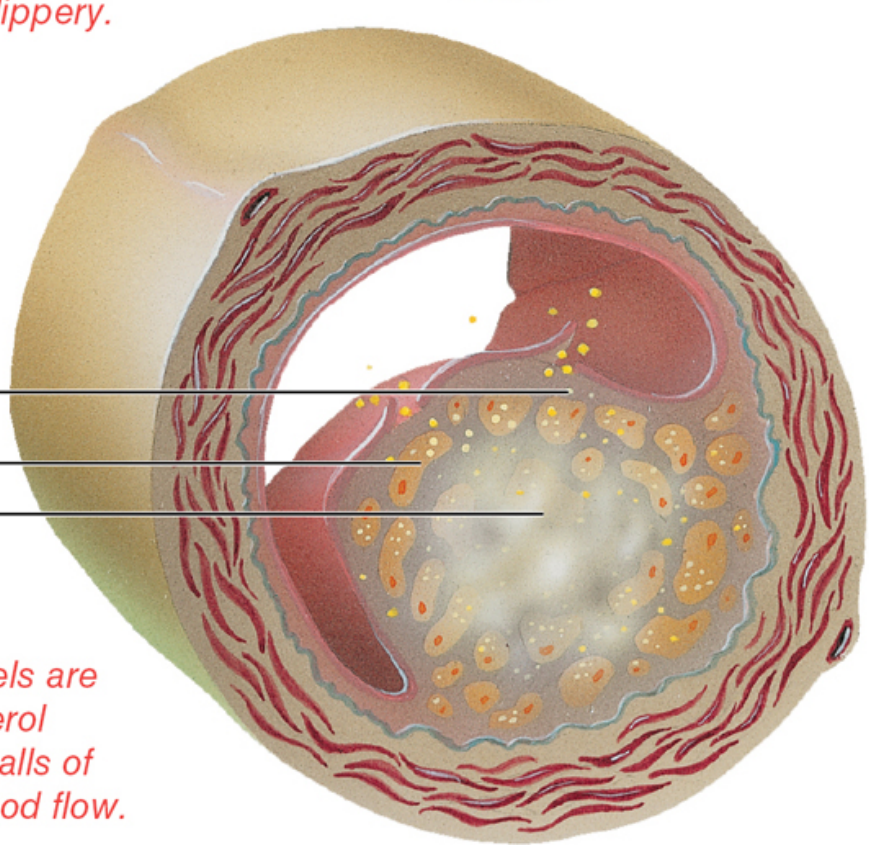
Atherosclerosis
A consequence of high cholesterol



Normal artery

Outer layer
Muscle layer
Lining

When the level of cholesterol in the bloodstream is normal, arterial walls remain smooth and slippery.



Clogged artery

LDL cholesterol
Foam cell
Plaque

When cholesterol levels are high, excess cholesterol accumulates in the walls of arteries, reducing blood flow.

Figure 12-3 Process of atherosclerosis. (Anatomical Chart Company. http://www.anatomical.com/.)

Traditional risk factors, such as smoking, hypertension, hyperlipidemia, diabetes, and obesity, are linked to the process of atherosclerosis by producing oxidative stress within the vasculature. Increased oxidative stress leads to progressive decreases in nitric oxide (NO) levels and endothelial dysfunction, enhancing atherosclerosis (**Fig. 12-4**).[8] In addition, diets typically seen in western industrialized countries have been linked to increased oxidative stress within the vasculature. This may partially explain the link between diet and atherosclerosis.[9] The role of a healthy lifestyle and diet is crucial in preventing the development or progression of CAD.

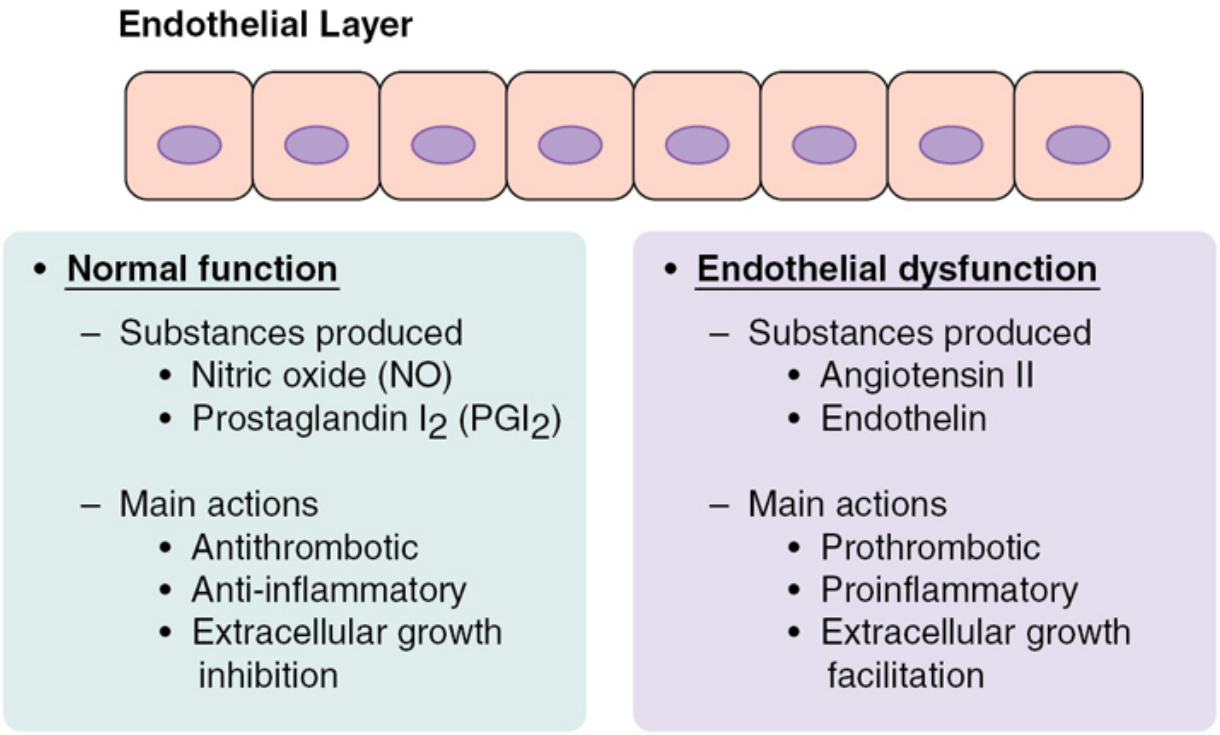


Figure 12-4 Endothelial function.

Although traditional risk factors have long been appreciated as the underlying cause for the development of CAD, continuing research efforts have attempted to identify novel risk factors to refine risk

assessment for the development of CAD. Potential candidates have included highly sensitive C-reactive protein, homocysteine, fibrinogen, and lipoprotein (a), among others.[10,11] Findings from the INTERHEART study indicate little may be gained from identifying additional risk factors.[12] In this large case–control study, nine clinical risk factors were strongly associated with the development of first-ever MI and accounted for >90% of the risk for developing CAD (**Table 12-1**). The results were consistent across sex, geographic regions, and ethnic groups, suggesting that strategies to reduce the incidence of CAD can be applied universally. Subsequent studies have verified the findings of INTERHEART, and many of these potential risk factors may indeed more accurately reflect the presence of CAD and be considered markers, as opposed to predicting who will subsequently exhibit CAD.[10,11,13]

Table 12-1

Risk Factors for First-Time Myocardial Infarction From the INTERHEART Study

Risk Factor	Adjusted Odds Ratio (99% Confidence Interval)
ApoB to apoA-1 ratio[a]	3.25 (2.81–3.76)
Current smoking	2.87 (2.58–3.19)
Psychosocial	2.67 (2.21–3.22)
Diabetes	2.37 (2.07–2.71)
Hypertension	1.91 (1.74–2.10)
Abdominal obesity	1.62 (1.45–1.80)
Moderate alcohol intake	0.91 (0.82–1.02)
Exercise	0.86 (0.76–0.97)
Vegetables and fruits daily	0.70 (0.62–0.79)
All combined	129.2 (90.2–185.0)

Apo, apolipoprotein.

[a]Risk of myocardial infarction increases with increased ratio.

INTERHEART study): case control study. *Lancet*. 2004;364(9438): 937–952. © 2004 Elsevier. With permission.

PLATELET AGGREGATION AND THE FORMATION OF THROMBI

Although coronary atherosclerosis is the underlying mechanism for most patients with anginal syndromes, thrombotic factors commonly play a key role in the pathogenesis of myocardial ischemia. Both blood flow turbulence and stasis can cause intermittent platelet aggregation or intermittent coronary artery thrombosis. Thus, platelet-active agents are used in the treatment of chronic stable angina.[14]

INTRACELLULAR SODIUM AND CALCIUM HANDLING

The late sodium current (I_{Na}) plays a role in the development and maintenance of myocardial ischemia. Most sodium enters the myocardium in phase 0 of the action potential. Under normal conditions, however, a small amount of sodium will enter the cell during phase 2 (plateau phase) of the action potential. When ischemia is present, sodium handling is altered such that a substantial increase occurs in the late I_{Na}. The increase in intracellular sodium triggers an increase in the influx of calcium through the reverse mode of the sodium–calcium exchanger. The net result of the alterations in intracellular ion handling is intracellular calcium overload.[5] Increases in intracellular calcium impair myocardial relaxation, increase intramyocardial wall tension, decrease perfusion to the myocardium owing to compression of the small arterioles feeding the myocardium, and increase myocardial oxygen demand.[15] Ultimately, these pathologic changes in sodium and calcium handling perpetuate and worsen ischemia once it develops. Targeting this pathologic process has led to the development of new antianginal medications (eg, ranolazine) with a distinct, novel mechanism of action compared with traditional antianginal agents (ie, nitrates, β-blockers, and calcium channel blockers [CCBs]).[5]

Clinical Presentation

A detailed description of chest pain is vital in order for the clinician to determine whether chest pain represents chronic stable angina, acute coronary syndrome (ACS), or is noncardiac in origin. Five key components commonly used to characterize chest pain include the location, duration, severity, and quality of pain as well as any factors that provoke and relieve the pain (**Table 12-2**). Chest pain stemming from myocardial ischemia is often described as a sensation of pressure or heavy weight located over the sternum. Patients may also report shortness of breath (SOB), nausea, vomiting, or diaphoresis. Pain may also occur in the neck, jaw, shoulder, or arm. The precipitation of pain is typically associated with exertion and rapidly resolves with rest or the administration of NTG. Chest pain that occurs at rest, prolonged in duration, or increased in severity is likely reflective of unstable disease and warrants immediate medical attention to prevent complications such as MI, HF, and death. Importantly, some patients (females, people with diabetes) may present with atypical symptoms such as indigestion or gastric fullness, or may present with diaphoresis alone without concomitant chest pain. Last, many episodes of ischemia are asymptomatic and termed as "silent ischemia."[1–3]

Table 12-2
Characteristics of Angina Pectoris

Symptoms
Sensation of pressure or heavy weight on chest alone or with pain
Pain described variably as feelings of tightness, burning, crushing, squeezing, vicelike, aching, or "deep"
Gradual increase in intensity followed by gradual fading away (distinguished from esophageal spasm)[a]
Shortness of breath with feeling of constriction about the larynx of upper trachea
Duration of Symptoms
0.5–30 minutes
Location of Pain or Discomfort

Over the sternum or very near to it
Anywhere between epigastrium and pharynx
Occasionally limited to the left shoulder and left arm
Rarely limited to right arm
Lower cervical or upper thoracic spine
Left interscapular or suprascapular area
Radiation of Pain
Medial aspect of left arm
Left shoulder
Jaw
Occasionally, right arm
Electrocardiogram
ST-segment depression >2 mm
T-wave inversion
Precipitating Factors
Mild, moderate, or heavy exercise, depending on the patient
Effort that involves the use of arms above the head
Cold environment
Walking against the wind
Walking after a large meal
Emotions: fright, anger, or anxiety
Coitus
Nitroglycerin Relief[a]
Relief of pain occurring within 45 seconds to 5 minutes of taking nitroglycerin

[a]Esophageal spasm and other gastrointestinal disorders occasionally mimic anginal pain and also can be relieved by nitroglycerin.

Physical findings in patients with chronic stable angina are often absent or nonspecific.[1]

Diagnosis and Risk Assessment

The evaluation of a patient presenting with chest pain suspected to be because of CAD should begin with a detailed history of ischemic symptoms and physical examination. Once this information is available, an estimate can be made of the probability of CAD being present (low, intermediate, high).[1] The probability estimate will often help direct which diagnostic tests are appropriate. Given that many symptoms associated with chronic stable angina are nonspecific, several noninvasive and invasive testing modalities are available to assist in the diagnosis and risk assessment of CAD.[1,2] It is important to discern as soon as possible whether the patient's reported chest discomfort is consistent with chronic stable angina or represents the presence of ACS. Patients presenting with ACS often are at high short-term risk of MI or death and warrant hospitalization with aggressive treatment strategies.[16,17] Lipid parameters, renal function, and fasting blood glucose levels, A_{1c}, should be obtained in all patients with suspected or established CAD to screen for metabolic abnormalities. High-sensitivity C-reactive protein (hsCRP) offers some prognostic value, but its value is uncertain. Other biochemical markers such as lipoprotein(a), lipoprotein-associated phospholipase A_2, and apolipoprotein B are not routinely recommended.[3]

A 12-lead ECG reading should be obtained in all patients with symptoms suggestive of angina pectoris. Although not useful in establishing a definitive diagnosis of CAD, the ECG will be useful at

detecting important information regarding conduction abnormalities, left ventricular hypertrophy, ongoing ischemia, or evidence of a previous MI. Chest radiography is not routinely recommended, except in patients with an abnormal ECG, history of MI, symptoms of HF, or ventricular arrhythmias.[1] Cardiac computed tomography angiography (CCTA) is a reasonable option to determine risk in patients whose ECG cannot be interpreted, who are unable to exercise to an appropriate workload, unable to perform stress testing, or alternatively to invasive coronary angiography in patients at moderate-to-high risk of unknown coronary anatomy.[1]

STRESS TESTING

The induction of stress via exercise or pharmacologic means is a common and highly useful procedure in the diagnosis of CAD. The test would be indicative of CAD if angina, ECG signs of ischemia, arrhythmias, abnormal heart rate, or abnormal blood pressure (BP) response develops. The product of the heart rate and systolic BP (ie, the rate–pressure or double product) correlates well with myocardial oxygen demand. The rate–pressure product normally rises progressively during exercise, with the peak value best describing the cardiovascular response to stress. Often, patients with stable angina experience chest pain at a consistent rate–pressure product.[18]

Abnormal responses of either BP or heart rate may signal CAD. A normal BP response to exercise is a gradual rise in systolic BP with the diastolic BP remaining unchanged. A rise or fall of diastolic BP >10 mm Hg is considered abnormal. A fall in systemic BP during exercise is especially ominous because this indicates that the cardiac output cannot increase sufficiently to overcome the vasodilation in the skeletal muscle vascular bed.[18]

Stress imaging studies, either echocardiographic or nuclear, are preferred over the exercise tolerance test in patients with left bundle-branch block, electronically paced ventricular rhythm, prior revascularization (percutaneous coronary intervention [PCI] or coronary artery bypass graft [CABG]), preexcitation syndrome, >1

mm ST-segment depression at rest, or other ECG conduction abnormalities. In addition, many patients are not able to exhibit an appropriate level of cardiac stress through exercise; pharmacologic stress testing is preferred in these patients.[1,18]

Pharmacologic stress may be achieved through the use of dipyridamole, adenosine, or dobutamine. Each of these agents is used to induce changes in the balance between myocardial oxygen supply and demand, similar to walking on a treadmill during the exercise stress test. Vasodilators (dipyridamole and adenosine) promote vasodilation in normal coronary segments but have no effect in arteries affected by atherosclerosis. The net result is shunting of blood away from diseased coronary arteries and the development of ischemia that may be detected by changes in BP, heart rate, or ECG changes. These agents are typically used in conjunction with myocardial perfusion scintigraphy. Stress thallium-201 myocardial perfusion imaging provides a dynamic picture of the heart. The radionuclide is injected at peak stress and an image is obtained within several minutes. A defect in myocardial uptake of the thallium indicates an area of ischemia or possible infarction.[19]

Dobutamine is a positive inotrope and typically is used with echocardiography. Administration of dobutamine leads to an increase in myocardial oxygen demand secondary to increases in heart rate and contractility. If demand exceeds the available oxygen supply, ischemia develops. Subsequent to the infusion of dobutamine, defects or decreases in the wall motion or thickening of the left ventricle are indicative of ischemia.[19]

CARDIAC CATHETERIZATION

CAD can be diagnosed definitively by coronary catheterization and angiography. In addition, angiography is the most accurate means of identifying less common causes of chronic stable angina, such as coronary artery spasm.[1] Cardiac catheterization is a procedure used to provide vascular access to the coronary arteries. Once access is gained with an intravascular catheter, a number of procedures (angiography, ventriculography, PCI) can be performed. Access to

the vasculature is usually obtained percutaneously through the radial, brachial, or femoral arteries. From this point, the catheter is advanced through the vasculature until the coronary arteries are accessible. After the tip of the catheter is advanced into the coronary arteries, dye is injected into the coronary arteries and the location and extent of atherosclerosis can be determined. Approximately 75% of patients with chronic stable angina are noted to have one-vessel, two-vessel, or three-vessel disease by this procedure (equally divided).[3]

The results of angiography can be useful in determining the risk of death or MI in patients with CAD and, subsequently, the course of needed treatment. For example, patients who have a significant stenosis in the left main coronary artery are at high risk of death and should undergo CABG.[20,21]

OVERVIEW OF DRUG AND NONDRUG THERAPY

The goals of therapy for chronic stable angina are to reduce or eliminate the symptoms of angina, to maintain or improve the quality of life, halt the progression of atherosclerosis, and prevent complications of the disease, such as MI and death, while minimizing health care costs. Both pharmacologic and nonpharmacologic interventions, in addition to myocardial revascularization procedures, are utilized simultaneously to achieve each of these goals.[1]

Vasculoprotective Therapy

LIFESTYLE MODIFICATIONS

Lifestyle modifications should always constitute a significant portion of any treatment plan for patients with chronic stable angina. Lifestyle modification should include adoption of a heart-healthy diet, smoking cessation/avoidance of second-hand smoke, adequate

physical activity, weight control, and maintenance of an acceptable waist circumference.[1,22,23] Dietary recommendations typically consist of limiting saturated fat, total fat, cholesterol, sodium, sugar-sweetened beverages, and red meat while consuming a diet high in fruits, vegetables, whole grains, omega-3 fatty acids, and fiber[22] (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). Adoption of a healthy dietary pattern reflective of these components has been demonstrated to have positive effects on cardiovascular risk factors.[1,22]

Smoking cessation is a crucial intervention as cigarette smoking (including second-hand smoke exposure) has been identified as the single most preventable cause of death because of CAD.[24] Clinicians should routinely assess the smoking status of patients with chronic stable angina and provide information regarding effective options to aid in smoking cessation. Nicotine replacement products, bupropion, and varenicline have been demonstrated as effective in assisting cessation efforts (see Chapter 91, Tobacco Use and Dependence). In addition to the avoidance of cigarette smoke, it is reasonable to recommend the avoidance of air pollution in patients with chronic stable angina. Unless contraindicated, it is appropriate to recommend one alcoholic beverage in females and one to two alcoholic beverages in males.[1]

A body mass index (BMI) of 18.5 to 24.9 kg/m^2 and a waist circumference <40 inches (101.60 cm) in males and 35 inches (88.90 cm) in females should be achieved or maintained. Adequate exercise facilitates both weight loss and better control of cardiovascular risk factors. Patients with chronic stable angina should be encouraged to engage in moderate-intensity exercise for 30 to 60 minutes per day for at least 5 days per week, but ideally each day. Weight loss can be facilitated through appropriate caloric restriction, as well as the adoption of healthy dietary eating patterns.[1]

RISK FACTOR MODIFICATION

In addition to appropriate lifestyle modifications, optimization of cardiovascular risk factors should be achieved. Although lifestyle

modifications may help improve risk factor control, pharmacotherapy may be required. **Table 12-3** provides appropriate targets for risk factor optimization. Appropriate identification and treatment of risk factors help prevent the development of CAD and disease progression in patients with existing CAD. Select drug therapies for each risk factor may be preferred because of their positive effects on the pathophysiology of atherosclerosis. Although several different classes of lipid-modifying drugs exist, 3-hydroxy-3-methylglutaryl co-enzyme A inhibitors (HMG-CoA reductase inhibitors, or statins) have been demonstrated in multiple trials to significantly reduce the progression of atherosclerosis, as well as reduce the incidence of death and MI.[25] In patients who require additional BP control after antianginal therapy has been optimized, angiotensin-converting enzyme (ACE) inhibitors may be preferred because of their theoretical potential to reduce the progression of CAD by improving endothelial function. Data suggest that angiotensin-receptor blockers (ARBs) may provide similar benefits in patients who cannot tolerate ACE inhibitors.[1,26] The presence of diabetes has been shown to be a significant risk factor for the development and progression of atherosclerosis; however, the majority of clinical trials demonstrate that tight glycemic control did not have a positive effect on the progression of atherosclerosis or reduce the risk of hard end points such as MI.[27] Information from the Diabetes Control and Complications Trial indicates that tight glycemic control with intensive insulin therapy in patients with type 1 diabetes significantly reduces the risk for MI and cardiovascular death.[28] Similar effects have not been seen in large randomized trials in patients with type 2 diabetes. In one large trial involving patients with CVD and type 2 diabetes, the use of intensive insulin therapy reduced nonfatal MI at 5 years, but total mortality was increased.[29] Given the available information, intensive glucose lowering cannot be recommended for patients with CAD and type 2 diabetes. Patients with type 2 diabetes should target a glycosylated hemoglobin (Hgb A_{1c}) <7%. The benefits in CVD of certain antihyperglycemic medications independent of A_{1c} lowering have been demonstrated and should be considered in patients with

both CVD and diabetes. Agents found to be beneficial for CVD include the sodium–glucose cotransporter 2 inhibitors empagliflozin, dapagliflozin, and canagliflozin and the glucagon-like peptide 1 receptor agonists liraglutide, semaglutide, and dulaglutide.[27]

Table 12-3

Recommendations for Risk Factor Optimization for Secondary Prevention in Patients with Coronary Heart Disease

Risk Factor	Intervention and Goal
Blood pressure	<130/80 mm Hg
	Use antihypertensives indicated for compelling indications as first-line therapy
Lipid management	High intensity, or maximally tolerated, statin
	Consider the addition of nonstatin therapy in very high-risk ASCVD when LDL-C remains ≥70 mg/dL
Diabetes	Hemoglobin A_{1c} <7%
	Sodium-glucose cotransporter 2 inhibitor or glucagon-like peptide 1 receptor agonist with demonstrated cardiovascular benefit
Smoking	Complete cessation with the help of pharmacological and behavioral strategies
	Avoid passive smoking
Dietary intake	High intake of fruits, vegetables, and whole grains
	Limit saturated fat to <10% of total calories
Physical activity	30–60 minutes of moderate physical activity (eg, brisk walking) for most days of the week
Weight management	BMI between 18.5 and 24.9 kg/m^2

ASCVD, atherosclerotic cardiovascular disease; BMI, body mass index; LDL-C, low-density lipoprotein cholesterol.

ANTIPLATELET THERAPY

Antiplatelet therapy has a central place in the treatment of patients with CAD. Aspirin (acetylsalicylic acid [ASA]) therapy has demonstrated a reduction in the incidence of MI and sudden cardiac death in patients with chronic stable angina. Aspirin's clinical efficacy in chronic stable angina, coupled with its minimal cost and demonstrated efficacy after MI, have made it the gold standard for antiplatelet monotherapy in patients with CAD. Current national guidelines from the American College of Cardiology (ACC)/American Heart Association (AHA) recommend an ASA dose of 75 to 162 mg daily for the prevention of MI and death. Although higher doses have been investigated in clinical studies, they have not shown increased efficacy but do increase the risk for adverse effects.[23]

Clopidogrel represents a suitable alternative antiplatelet agent to prevent MI and death in chronic stable angina patients unable to take ASA. The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial demonstrated that clopidogrel significantly reduced the incidence of stroke, MI, or vascular death in patients with atherosclerotic vascular disease (previous MI, stroke, or peripheral arterial disease [PAD]) compared with ASA. In addition, clopidogrel was well-tolerated with the major adverse effects noted to be gastrointestinal (GI) intolerance and rash. Despite the significant results, the absolute difference in the primary outcome between the two strategies was quite small (0.4%, number need to treat = 200).[30] As such, clopidogrel remains a second-line choice behind ASA in patients with CAD. Clopidogrel should be administered at a dosage of 75 mg/day.

The approach of dual antiplatelet therapy (DAPT), combining ASA with a $P2Y_{12}$ antagonist (clopidogrel, prasugrel, or ticagrelor), has been demonstrated to improve morbidity and mortality in a number of patients at high risk of CVD.[16,17] Given the different mechanisms of antiplatelet effect, combining aspirin with a $P2Y_{12}$ antagonist might be expected to provide additional protection from MI and death in patients with stable CAD as compared to monotherapy. The Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance trial assessed the utility of long-term DAPT in patients with documented CAD or with multiple cardiovascular risk factors. The combination of ASA plus clopidogrel for 28 months did not reduce the risk of death, MI, stroke, or coronary revascularization as compared to ASA alone. However, dual therapy did increase the risk of bleeding.[31]

A post hoc analysis revealed a reduction in ischemic risk in patients with prior MI, suggesting that some patients may benefit from long-term DAPT.[31] The Pegasus-TIMI 54 trial evaluated the role of DAPT (low-dose ASA plus either ticagrelor 90 or 60 mg bid vs ASA alone) in patients with a prior MI in the previous 1 to 3 years.[32] The median time from MI to randomization was 1.7 years. In over 21,000 patients with a median follow-up of 33 months, ASA plus both doses of ticagrelor reduced the primary end point (cardiovascular death, MI, stroke) compared to ASA monotherapy. This reduction came at the expense of an increased risk of bleeding, with TIMI major bleeding occurring at a rate of 2.6% and 2.3% in the groups receiving ticagrelor 90 and 60 mg bid, as compared to 1.06% in patients receiving placebo.[32]

In a separate investigation, patients who received an additional 18 months of DAPT as compared to the standard duration of 12 months in patients who received drug-eluting stents (DESs) had a lower rate of stent thrombosis (0.4% vs 1.4%, $P < .001$) and major adverse cardiovascular and cerebrovascular events (4.3% vs 5.9%, $P < .001$), which included a reduction in MI.[33] There was an increase in moderate-to-severe bleeding (2.5% vs 1.6%, $P < .001$). Up to 40% of the 9961 patients underwent PCI because of chronic stable angina,

and DAPT either consisted of ASA plus clopidogrel or ASA plus prasugrel.[33] The duration of DAPT must be individualized. Whereas patients with stable IHD that are not post-MI or post-PCI do not require DAPT, some patients may receive extended durations of DAPT if they have a previous history of prior MI or are post-PCI and have received a DES.[34]

Anti-ischemic Pharmacotherapy

Historically, agents used in the treatment of patients with chronic stable angina primarily affected either determinants of myocardial oxygen supply or myocardial oxygen demand, or both. Within this paradigm, β-blockers, CCBs, and chronic nitrate therapy have demonstrated effectiveness in the prevention of ischemic symptoms. In January 2006, the U.S. Food and Drug Administration (FDA) granted approval to ranolazine. Unlike traditional anti-anginal medications, ranolazine does not affect heart rate or BP. The selection of specific anti-ischemic pharmacotherapy for patients with chronic stable angina should take into account relevant patient characteristics as well as guideline recommendations.

β-BLOCKERS

β-Blockers lower myocardial oxygen demand primarily by lowering heart rate and myocardial contractility. Neither β-selectivity nor the presence of α-1 blockade appear to vary efficacy at preventing ischemia, and, therefore, the choice of a specific agent for a given patient will likely depend on cost, number of daily doses, and the presence of other comorbid conditions. β-Blockers with intrinsic sympathomimetic activity are not routinely used in patients with stable angina because of reduced efficacy. The dose of the β-blocker should be titrated to a goal resting heart rate of 55 to 60 beats/minute and therefore will be patient-specific.[2] β-Blockers should be avoided in patients with primary vasospastic angina and may worsen symptoms in patients with reactive airway disease or PAD. The most common side effects observed with chronic therapy

include bradycardia, hypotension, fatigue, and sexual dysfunction. Other conditions that may prevent the use of β-blocker therapy include severe bradycardia or atrioventricular (AV) nodal conduction defects.[35–37]

NITRATES

Nitrates are available in a number of different formulations, and available options are listed in **Table 12-4**. Regardless of the formulation, all nitrate options are effective at preventing or relieving ischemic symptoms if used appropriately, including the use of a nitrate-free interval. Nitrates can increase myocardial oxygen supply through vasodilation of the coronary arteries, as well as reduce myocardial oxygen demand through the reduction of preload. Nitrates produce vasodilation through the biotransformation and the release of NO.[38] Long-acting nitrates are effective agents for the prevention of anginal symptoms. Sublingual NTG is a vital agent to treat acute anginal attacks. Common side effects of nitrate therapy include hypotension, dizziness, and headache. Headache often will resolve with continued therapy and may be treated with acetaminophen. Concomitant administration with phosphodiesterase type-5 inhibitors (within 24 hours for sildenafil and vardenafil, 48 hours for tadalafil) is contraindicated because of the risk of life-threatening hypotension.[38,39]

Table 12-4
Commonly Prescribed Organic Nitrates

Drug	Dosage Form	Duration	Onset (Minutes)	Usual Dosage
Short-Acting				
NTG	SL	10–30 minutes	1–3	0.4–0.6 mg[a,b]
NTG	Translingual spray	10–30 minutes	2–4	0.4 mg/metered spray[a,b]
NTG	IV	3–5 minutes[c]	1–2	Initially 5 μg/minute. Increase every 3–5 minutes until pain is relieved or hypotension occurs
Long-Acting[d]				
NTG	SR capsule	4–8 hours	30	6.5–9 mg every 8 hours
NTG	Topical ointment[e]	4–8 hours	30	1–2 inches every 4–6 hours[f]
NTG	Transdermal patch	4 to >8 hours	30–60	0.1–0.2 mg/hour to start; titrate up to 0.8 mg/hour[f]
NTG	Transmucosal	3–6 hours	2–5	1–3 mg every 3–5 hours[f]
ISDN	SL	2–4 hours	2–5	2.5–10 mg every 2–4 hours[f]
	Chewable	2–4 hours	2–5	5–10 mg every 2–4 hours[f]
	Oral	2–6 hours	15–40	10–60 mg every 4–6 hours[f]
	SR capsule	4–8 hours	15–40	40–80 mg every 6–8 hours[f]
ISMN[g]	Tablet (ISMO, Monoket)	7–8 hours	30–60	10–20 mg bid (morning and midday) to start; titrate to 20–40 mg bid[f]
	Extended-release tablet (Imdur)	8–12 hours	30–60	60 mg every day to start; titrate to 30–120 mg every day

bid, two times daily; ISDN, isosorbide dinitrate; ISMN, isosorbide monohydrate; IV, intravenous; NTG, nitroglycerin; SL, sublingual; SR, sustained release.

[a]When using sublingual or translingual spray forms of NTG, patients should administer the dose while sitting to minimize tachycardia, hypotension, dizziness, headache, and flushing. The optimal dose relieves symptoms with <10 to 15 mm Hg drop in systolic blood pressure or <10 beats/minute rise in pulse. Pain relief is rapid (onset 1–2 minutes; relief in 3–5 minutes), but up to three doses at 5-minute intervals may be given. After this, medical assistance should be summoned.

[b]Sublingual NTG tablets are degraded rapidly by heat, moisture, and light. They should be stored in a cool, dry place; do not leave the lid open or refrigerate. Tablets should be stored in the original manufacturer's container or a glass vial because the tablets volatilize and bind to many plastic vials and cotton. Previously, stinging of the tongue was an indicator of fresh tablets, but newer formulations only cause stinging in ~75% of patients.

[c]Duration after infusion discontinued.

[d]Longer-acting forms of nitrates are effective drugs, but it is important to understand their limitations to optimize effectiveness. Sublingual ISDN tablets display an onset and duration intermediate between that of sublingual NTG and oral ISDN. Because of high presystemic (first-pass) metabolism of the oral forms of both NTG and ISDN, very large doses may be required compared with SL or chewable dosage forms. Small oral doses (2.5 mg NTG, 5 mg ISDN) are probably not effective; doses as large as 9 mg NTG and 60 mg ISDN are not uncommon. Despite claims for longer activity, ointments and oral forms are often only effective for 4 to 8 hours, even when given as SR preparations. Also, continued daily use leads to rapid development of tolerance (see note f).

[e]Squeeze 1 to 2 inches of ointment onto the calibrated paper enclosed in the package with tube. Carefully spread the ointment on chest in a thin layer ~2 inches by 2 inches in size. Keep area covered with applicator paper. Wipe off previous dose before adding new dose or if hypotensive. If another person applies the ointment, avoid contact with fingers or eyes to prevent headache or hypotension.

[f]Dosage regimens should maintain a nitrate-free interval (eg, bedtime) to decrease tolerance development. Give last oral dose or remove ointment or transdermal patch at 7 PM. Give last dose of SR ISDN in early afternoon.

[g]Major active metabolite of ISDN; 100% bioavailable; no first-pass metabolism, but tolerance may still occur. Rapid-release form (ISMO, Monoket) as 10 and 20 mg tablets. Extended-release form (Imdur) as 60 mg tablets. Okay to cut Indur in half, do not crush or chew.

CALCIUM CHANNEL BLOCKERS

CCBs are highly diverse compounds. They differ markedly in chemical structure as well as specificity for cardiac and peripheral tissue. Using these characteristics, it is possible to classify CCBs into subtypes (**Table 12-5**).[40]

Table 12-5
Calcium Channel Blockers in Anginal Syndromes

Drug Name	FDA Approved[a]	Usual Dose for Chronic Stable Angina[b]	Product Availability
Dihydropyridines			
Amlodipine	Angina, hypertension	2.5–10 mg every day	2.5, 5, 10 mg tab
Felodipine	Hypertension	5–20 mg every day	5, 10 mg ER tab
Isradipine	Hypertension	2.5–10 mg bid	2.5, 5 mg IR cap
		5–10 mg every day	5, 10 mg CR tab
Nicardipine	Angina (IR only), hypertension	20–40 mg tid	20, 30 mg IR cap
		30–60 mg bid	30, 45, 60 mg SR cap
Nifedipine	Angina, hypertension	10–30 mg tid	10, 20 mg IR cap
		30–180 mg every day	30, 60, 90 mg ER tab
Nisoldipine	Hypertension	20–60 mg every day	10, 20, 30, 40 mg ER tab
Diphenylalkylamines			
Verapamil	Angina, hypertension, SVT	30–120 mg tid/qid	40, 80, 120 mg IR tab
		120–240 mg bid	120, 180, 240 mg SR tab
		120–480 mg every HS	180, 240 mg DR, ER tab
			120, 180, 240, 360 mg ER cap
			100, 200, 300 mg DR, ER tab
Benzothiazepines			
Diltiazem	Angina, hypertension, SVT	30–120 mg tid/qid	30, 60, 90, 120 mg IR tab
		60–180 mg bid	60, 90, 120, 180 mg SR cap
		120–480 mg every day	120, 180, 240, 300, 360 mg cap
			120, 180, 240 mg ER cap
			120, 180, 240, 300, 360, 420 mg ER cap

bid, two times a day; cap, capsules; CR, controlled-release; DR, delayed-release; ER, extended release; FDA, U.S. Food and Drug Administration; HS, bedtime; IR, immediate release; qid, four times a day; SR, sustained release; SVT, supraventricular including atrial fibrillation, atrial flutter, and reentry; tab, tablets; tid, three times a day.

[a]FDA-approved indications vary among IR and ER products. However, most or all have been used clinically for both angina and hypertension. Avoid IR products in hypertension.

[b]Because of short half-lives, most of these drugs are given tid if using IR tabs or caps. Amlodipine has a long half-life and is given once daily.

Both non-dihydropyridine CCBs (non-DHP CCBs), diltiazem and verapamil, exert similar effects on myocardial and peripheral tissue. They slow conduction and prolong the refractory period in the AV node (see Chapter 15, Cardiac Arrhythmias). Both agents can depress myocardial contractility and are moderate peripheral vasodilators and potent coronary artery vasodilators.[40]

In contrast to diltiazem or verapamil, the dihydropyridines (DHPs) such as nifedipine, amlodipine, felodipine, isradipine, and nicardipine do not slow cardiac conduction. They are more potent peripheral

vasodilators and may be associated with a reflex increase in the heart rate. The net effect of these actions results in no or minimal depression of myocardial function (see Chapter 14, Heart Failure).[40]

Both DHP and non-DHP CCBs produce an increase in myocardial oxygen supply through vasodilation of the coronary arteries, as well as reduce myocardial oxygen demand through lowering of intramyocardial wall tension (by lowering systemic BP). However, non-DHP CCBs would be expected to lower myocardial oxygen demand to a greater degree because of additional reductions in heart rate and contractility. Although defined as being within the same pharmacologic class, it is important to consider DHPs and non-DHPs separately when considering their use in patients with chronic stable angina. The reductions in heart rate and contractility with non-DHPs may be beneficial for some patients, although detrimental in others such as patients with compromised left ventricular (LV) function or bradycardia at baseline. Conversely, amlodipine and felodipine have been shown to be safe to use in patients with LV dysfunction and to provide a reasonable option for the prevention of ischemic symptoms in those patients.[40] CCB should be used cautiously when used in combination with cyclosporine, carbamazepine, lithium, amiodarone, and digoxin. Non-DHP CCB should be avoided in most situations because of the duplicate effects on heart rate and cardiac contractility.[1] Side effects of CCB therapy depend on the specific agent used. Use of non-DHP CCBs may result in bradycardia, hypotension, and AV block. Patients receiving DHP CCBs may experience reflex tachycardia, peripheral edema, headache, and hypotension.[3]

RANOLAZINE

Ranolazine is an anti-ischemic agent that inhibits the late sodium current, thereby reducing intracellular sodium. During myocardial ischemia, sodium influx is increased, leading to intracellular calcium overload through the sodium/calcium exchanger. An excess of intracellular calcium leads to changes that promote and worsen ischemia, such as increased intramyocardial wall tension and

reduced microvascular perfusion. By inhibiting sodium influx, ranolazine prevents ischemia-induced contractile dysfunction and delays the onset of angina. A key distinction between ranolazine and traditional antianginal agents is that it has no appreciable effect on heart rate and BP. The lack of significant hemodynamic effects makes the drug useful in patients in need of further antianginal therapy but who have low BP or heart rates preventing titration of conventional antianginal agents.[41]

Initial clinical trials demonstrated that ranolazine was an effective agent at reducing anginal episodes when added to existing therapy with CCBs or long-acting nitrates. Subsequent investigations demonstrated long-term safety and efficacy. Common adverse effects include headache, constipation, dizziness, and nausea. The drug is extensively metabolized in the liver through both cytochrome P-450 enzymes CYP3A4 and CYP2D6; therefore, attention should be paid to potential drug interactions. CYP3A4 appears to be the major pathway for metabolism and use of ranolazine is contraindicated in patients with significant hepatic dysfunction and in those receiving potent inhibitors and inducers of CYP3A4 such as ketoconazole or rifampin, respectively.[41]

Myocardial Revascularization

Revascularization of the myocardium, with CABG or PCI, is a mainstay in the treatment of patients with CAD. The goals of revascularization do not differ from the overall goals in treating patients with chronic stable angina, namely, to relieve symptoms, improve quality of life, and prevent MI and death. Historically, a great deal of focus was devoted to comparing CABG, PCI, and medical management and their relative efficacy in relieving symptoms and improving prognosis. In a broad population of patients with CAD, revascularization with either CABG or PCI was found to be superior to medical management therapy alone at relieving symptoms at 1 year, although there was no difference in overall mortality between the treatment strategies.[42] However, CABG therapy tended to be

superior at providing long-term relief of symptoms, as well as providing a lower need for repeat revascularization therapy compared to PCI. When considering subgroups of patients with more severe disease or who have manifested LV dysfunction, differences in long-term mortality can be observed among the different treatment strategies. In patients with double-vessel or triple-vessel disease, significant disease of the left main artery, or LV dysfunction, CABG therapy has been demonstrated to provide a reduced 5-year mortality rate compared with PCI or medical therapy alone.[21]

Despite the availability of data regarding the relative effects of PCI, CABG, and medical management on morbidity and mortality, there has been a dramatic increase in the use of PCI in recent years. CABG remains the preferred strategy for patients with three-vessel disease or who have multivessel disease plus LV dysfunction. In patients with less severe CAD, PCI can be expected to provide similar benefits in mortality as compared to CABG but may not be as effective at reducing symptoms or the need for repeat revascularization procedures. Recent investigations have indicated that aggressive medical treatment, including intensive lipid-lowering therapy, may be as effective as PCI at improving prognosis over the long term, but may be inferior at reducing symptoms of angina.[1,43,44] These trials are significant in that they highlight the importance of implementing effective strategies, which reduce the progression of CAD, regardless of whether revascularization therapy is utilized. Relevant issues facing pharmacists today not only include optimizing the medical management of CAD but also providing effective pharmacotherapy to prevent complications of PCI.

CASE 12-1

Question 1: J.P., a 62-year-old dairy farmer, is hospitalized for evaluation of chest pain. About 3 weeks before admission, he noted substernal chest pain brought on by lifting heavy objects or walking uphill. He describes a crushing or viselike pain that never occurs at rest and is not associated with meals, emotional stress, or a particular time of day. When J.P. stops working, the pain subsides in about 5 minutes.

J.P.'s mother and brother died of a heart attack at ages 62 and 57, respectively; his father, who is alive at age 86, has survived one heart attack and one stroke. Family history is negative for diabetes mellitus. J.P. is 70 inches (177.80 cm) tall and weighs 235 pounds (106.59 kg); he drinks two or three beers a day and does not smoke or chew tobacco.

J.P.'s other medical problems include a 10-year history of hypertension and diabetes for 4 years. Until 3 weeks ago, J.P. could perform all his farm chores without difficulty, including heavy labor. He follows a no-added-salt diet, but consistently eats at fast-food establishments with his favorite meal consisting of two cheeseburgers and French fries.

J.P.'s medication history reveals the following: lisinopril 10 mg once daily, metformin 500 mg bid, and hydrochlorothiazide 25 mg once daily. He rarely uses over-the-counter (OTC) medications. He has an allergy to sulfamethoxazole.

On admission to the cardiac ward, J.P. appears his stated age and is in no apparent distress. Resting vital signs include supine BP, 145/95 mm Hg (last ambulatory visit, 130/85 mm Hg); regular pulse, 84 beats/minute (last ambulatory visit, 78 beats/minute), and respiratory rate, 12 breaths/minute. He has no peripheral edema or neck vein distension, and lung auscultation is within normal limits. Abdominal examination is unremarkable, and he is alert and oriented three times. Cardiac auscultation reveals a regular rate and rhythm with a normal S_1 and S_2; third or fourth heart sounds and murmurs are not noted. A 12-lead ECG reveals normal sinus rhythm at a rate of 84 beats/minute without evidence of previous MI. All intervals are within normal limits.

Admitting laboratory values include the following:

Hct, 43.5%
White blood cell (WBC) count, 5000/mL
Sodium (Na), 140 mEq/L
Potassium (K), 4.7 mEq/L
Magnesium (Mg), 1.9 mEq/L
Random blood glucose, 132 mg/dL
Hgb A_{1c}, 7.4%
Blood urea nitrogen, 27 mg/dL
Serum creatinine, 1.4 mg/dL
Urinary albumin–creatinine ratio, 27 mg/mmol

Chest radiograph is within normal limits.

What signs and symptoms does J.P. exhibit that are consistent with the diagnosis of chronic stable angina?

CLINICAL PRESENTATION OF CHRONIC STABLE ANGINA

J.P.'s description of his chest pain includes several common characteristics of angina pectoris (see Table 12-2).[1–3] The substernal location of J.P.'s chest pain is typical, although some patients describe pain radiating down the left arm or pain that is referred to the shoulder area or jaw. J.P.'s pain is described as crushing or viselike in quality, which also is common; a fullness in the throat or jaw may occur simultaneously or in lieu of chest pain. In some cases, the patient may not consider these sensations as pain, describing them instead as a sense of pressure or heaviness. Many patients report SOB. J.P.'s symptoms are related to exercise and exertion—both known precipitating factors of angina. Most episodes of exertional angina last several minutes in duration and are relieved with rest. Because J.P. has never sought medical attention for his chest pain, his response to NTG cannot be determined.

After getting a detailed description of J.P.'s symptoms, his physician can characterize his chest pain and make a global assessment. Initially, the chest pain should be classified as either typical angina, atypical angina, or noncardiac chest pain. Furthermore, angina should also be classified as either stable or unstable. This distinction is important because it indicates whether his short-term risk of an acute coronary event could be life-threatening. Attempts to categorize J.P.'s anginal symptoms on an objective measurement scale (eg, Canadian Cardiovascular Society Grading Scale) can be misleading.[45] For example, a sedentary 65-year-old patient's class II symptoms may be tolerable, but the same symptoms could significantly disable an active 50-year-old patient.

J.P.'s chest pain is of a quality and duration characteristic of angina, provoked by exertion, and relieved by rest; therefore, J.P.'s constellation of symptoms can be classified as typical chest pain. J.P.'s symptoms do not occur at rest; however, they should be classified as stable angina.[1–3]

Case 12-1, Question 2: Assess J.P.'s physical examination. What signs and symptoms are relevant to the angina?

The physical examination typically provides little information about the presence of CAD. The most useful findings pertain to the cardiovascular system where heart rate and BP can be increased during an acute anginal episode. J.P.'s physical examination is characteristic of a male of his age with angina.[3] He is obese and hypertensive, but his cardiac examination is normal. The presence of murmurs would have required further workup; the absence of a third heart sound suggests that the left ventricle may be functioning normally (see Chapter 14, Heart Failure, for a description of third heart sounds). The absence of a fourth heart sound in J.P. is indicative of a low probability of cardiac end-organ damage resulting from systemic hypertension. His chest radiograph, which is normal, does not present evidence of other complications commonly associated with myocardial ischemia (eg, enlarged heart, HF).

J.P.'s physical examination should also evaluate the possibility of the presence of atherosclerosis in other major vascular beds (peripheral vascular disease, cerebrovascular disease, abdominal aortic aneurysm). The presence of xanthomas would suggest severe hypercholesterolemia, but these were not noted in J.P.

Diagnostic Procedures

Case 12-1, Question 3: What other objective diagnostic procedures are helpful to confirm CAD and angina in J.P.?

A 12-lead ECG indicates there is no ongoing ischemia at this time. As such, it does not help confirm the diagnosis of CAD. An echocardiogram could be used to better assess cardiac structure and function, including ruling out other potential causes for myocardial ischemia such as valvular dysfunction or pericardial disease, but would not definitively confirm the presence of CAD.

Electron bean computed tomography or CCTA could be used to detect the presence of coronary atherosclerosis, but in J.P. would not offer vital prognostic information available with other testing modalities.[1]

Given J.P.'s current lifestyle and activity level, he would likely be able to tolerate exercise treadmill testing. Treadmill testing would be an appropriate initial diagnostic modality in J.P. because of its noninvasive nature, reliability with established protocols, as well as the ability to offer prognostic information regarding the risk of MI and death for J.P. Therefore, stress testing, in this case with exercise treadmill versus pharmacologic means, is an excellent initial diagnostic modality to use in J.P.

Case 12-1, Question 4: Should J.P. undergo cardiac catheterization? How will the results of this invasive procedure influence future therapy?

Coronary catheterization and angiography are the best tests for the definitive diagnosis of CAD. In addition, angiography is the most accurate means of identifying less common causes of chronic stable angina, such as coronary artery spasm.[1] Although angiography is effective at identifying flow-limiting atherosclerotic plaques in the coronary vasculature, it cannot provide information on whether those lesions are causing clinical symptoms. Stress testing is often a more appropriate initial modality to first characterize the myocardial ischemia that takes place with exertion. Patients with significant ischemia via stress testing should then undergo cardiac catheterization to determine the nature and extent of disease. The results of angiography will be useful in determining the risk of death or MI in J.P. and, subsequently, the course of needed treatment. For example, patients who have a significant stenosis in the left main coronary artery are at high risk of death and should undergo CABG.[20]

Risk Stratification and Prognosis

Case 12-1, Question 5: After having a positive treadmill stress test and undergoing subsequent cardiac catheterization, J.P. is found to have two-vessel CAD with obstructive lesions of 55% and 70% in the right coronary artery (RCA) and circumflex arteries, respectively; the left anterior descending (LAD) coronary artery is not involved. What is his prognosis?

The prognosis of patients with stable angina is variable and dependent on the presence of other factors and comorbid conditions. The extent of CAD, quantification of ventricular function, the response to stress testing, and the initial clinical evaluation all help to provide an estimate of risk in a given patient. Developing a level of risk for a particular patient helps determine the appropriate treatment strategy.[1,2]

J.P.'s history and physical examination suggest he does not have HF; poor LV function would be an ominous concurrent finding. J.P. also does not have three-vessel disease or blockage of the LAD artery. J.P. does have type 2 diabetes, which elevates his risk for future cardiovascular events. The absence of other major comorbid conditions and myocardial dysfunction, along with the current extent of CAD, indicates that J.P.'s prognosis at this time is favorable provided he initiate appropriate treatment strategies demonstrated to reduce morbidity and mortality in patients with CAD.[1,2]

Medical Management of Chronic Stable Angina

Case 12-1, Question 6: How should J.P. be managed at this time? Should he undergo revascularization with PCI or CABG or be managed medically?

As discussed, goals for managing CAD and angina in J.P. include relief of symptoms and reduction of myocardial ischemia to improve quality of life, as well as prevention of major complications of CAD such as acute MI and death.[1] Depending on the patient, both goals may be accomplished through revascularization (surgical or percutaneous), medical management, or both. Regardless of the

treatment strategy chosen to relieve ischemic symptoms, therapies that prevent death (vasculoprotective agents) should receive priority.

Presently, CABG is not the best option for J.P. because the usual indications for surgical therapy include presence of left main CAD, presence of three-vessel disease (especially if LV function is impaired), or ineffectiveness of medical therapy.[1,20] However, revascularization with PCI is a potential option along with medical management alone. Although PCI would offer no mortality advantage over medical therapy at this time, it has been shown to decrease the incidence of recurrent symptoms in the short term (1 year).[1] If J.P. can implement aggressive lifestyle modifications and control of risk factors, progression of CAD and control of ischemic symptoms will be similar to PCI within a 5-year time frame.[42] Both strategies, including the pros and cons of PCI or medical management alone, should be offered to J.P. so that an informed decision can be made in accord with his wishes. Overall, J.P. will probably do well with medical therapy. His life expectancy depends on the progression of the disease and development of other complications of CHD (HF, MI, sudden cardiac death).

RISK FACTORS AND LIFESTYLE MODIFICATIONS

Case 12-1, Question 7: What independent risk factors for CAD are present in J.P.? Which of these may be altered?

The first step in the treatment of any patient with chronic stable angina or CAD should be the modification of any existing risk factors and the adoption of a healthy lifestyle. By addressing the underlying circumstances, which likely led to the development of CAD, a significant impact can be made at halting the progression of the disease and preventing complications of CAD. Current recommendations for the goals for risk factor management are listed in Table 12-3.[23,25,26] In addition to specific risk factor goals, attention should be paid to evidence that favors specific drug therapies that have evidence supporting reductions in morbidity and mortality.

Examples would include the use of HMG-CoA reductase inhibitors in the treatment of hyperlipidemia,[1,2] as well as the use of ACE inhibitors for the treatment of hypertension.[25,26]

J.P. has several risk factors for CAD, some of which cannot be altered, such as middle age, male sex, and a strong family history of CAD. Risk factors, such as hypertension, obesity, hypercholesterolemia, smoking, and possibly stress, can potentially be modified to decrease the likelihood of adverse sequelae for J.P. His hypertension should be controlled, and statin therapy should be initiated (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease). A fasting Hgb A_{1c} should be drawn with a goal of <7% (see Chapter 53, Diabetes Mellitus). Dietary modification and weight reduction for J.P. are mandatory because they positively influence several risk factors. J.P., however, does not smoke cigarettes, which would significantly increase his cardiovascular risk.[1,22] J.P.'s active lifestyle may influence his prognosis favorably.[1]

DIETARY INTERVENTIONS

CASE 12-1, QUESTION 8: Are there any dietary patterns that J.P. can adopt that have demonstrated reductions in cardiovascular end points?

Although the positive effects of lifestyle modifications on cardiovascular risk factors are well-recognized, the effect of specific lifestyle interventions on reducing hard cardiovascular end points can be underappreciated. The adoption of a healthy dietary pattern is one such example. Randomized controlled trials have demonstrated that the adoption of the Mediterranean diet (diets emphasizing whole grains, fruit, vegetables, nuts and legumes, moderate dairy intake, moderate amounts of lean protein, and polyunsaturated fats) reduced the relative risk of MI or cardiac death by 50% to 73% as compared to a diet similar in composition to the AHA Step I diet.[46] It is important to note that in one of these studies, the Lyon Diet Heart Study, the improvements in cardiovascular

morbidity and mortality occurred without significant changes in the lipid profiles of study subjects.[46] One trial found the Mediterranean diet supplemented with either nuts or olive oil reduced cardiovascular events in patients at high risk of CVD when compared to a low-fat diet.[47] Several additional trials demonstrated that patients with a history of MI who increased their intake of either fatty fish or ingested omega-3 fatty acid fish oil supplements also had reductions in cardiovascular death and MI as compared to control patients without dietary intervention.[48] Lastly, epidemiologic studies have confirmed the results from randomized controlled trials showing that adherence to a Mediterranean diet significantly reduces cardiovascular morbidity and mortality.[46] A Mediterranean diet reduces systemic inflammation as measured by C-reactive protein, reduces the incidence of insulin resistance, and improves endothelial function. Although a great deal of attention has been directed at the increased intake of omega-3 polyunsaturated acids (eicosapentaenoic acid and docosahexaenoic acid derived from fish or α-linoleic acid derived from plants) being responsible for the observed benefits in each of these trials, multiple dietary alterations were likely in play. The results should be interpreted as the result of the adoption of a healthy dietary pattern.[22]

Case 12-1, Question 9: J.P. states he had heard that antioxidants such as vitamin E could benefit him along with a daily B vitamin. Would these supplements offer significant cardiovascular benefit for J.P.?

Because oxidation of low-density lipoprotein (LDL) in the arterial wall is a key step in the atherosclerotic process, considerable interest exists in the theory that supplementation with high doses of antioxidants such as vitamin E, vitamin C, and β-carotene might mitigate this process and slow the progression of atherosclerosis. Multiple large randomized studies have shown no positive effect from supplemental intake of antioxidants such as vitamin E on the incidence of cardiovascular outcomes including MI or death.[1,49] These findings were observed in both primary and secondary

prevention of cardiovascular events. J.P. should be informed that supplemental intake of vitamin E will not have any positive effect on his CVD.

Interest in the use of supplemental intake of folic acid and B vitamins stems from their ability to lower homocysteine levels. It is well-established that elevated levels of homocysteine are associated with a higher incidence of CVD.[50] Despite this association, the great majority of appropriately designed, randomized, placebo-controlled studies have demonstrated that supplemental ingestion of folic acid and B vitamins has no impact in reducing cardiovascular outcomes such as MI or death.[1,51] Therefore, similar to the advice for vitamin E, J.P. should be counseled that folic acid and B vitamin supplementation will not provide any tangible cardiovascular benefit.

Anti-ischemic Drug Therapy

SUBLINGUAL NITROGLYCERIN

Case 12-1, Question 10: Should J.P. receive a prescription for SL NTG on discharge from the hospital? If so, what education should J.P. receive with regard to the use and storage of SL NTG?

All patients with CAD, especially those with chronic stable angina, should receive a prescription for SL NTG for the treatment of acute anginal attacks.[38,39] NTG leads to vasodilation of both veins and arteries that reduces myocardial oxygen demand, thereby relieving angina. Because response to NTG varies among patients, the dosage should be individualized (Table 12-4). Most patients, however, use a dose of 0.4 mg. The administration of sublingual NTG is also useful in patients who have a good understanding of what level of exertion produces their chest pain. About 5 to 10 minutes before J.P. is about to undergo heavy exertion, he can take a sublingual NTG tablet to prevent angina.[1]

Patient education is a crucial component of ensuring SL NTG is used appropriately to treat acute anginal attacks. When angina

occurs, J.P. should sit down immediately and utilize his SL NTG. If using tablets, he should place the NTG tablet under his tongue; he should not swallow it. If using the NTG spray, he should apply the spray on or under the tongue and not swallow or inhale it. Many patients experience dizziness and light-headedness, which is minimized by sitting. The onset of action is within 1 to 2 minutes, and pain usually is relieved within 3 to 5 minutes. If the pain persists or is unimproved 5 minutes after the first dose of NTG, the patient should call 9-1-1 as they may be experiencing an MI.[1] If he needs more than one dose, he can take a maximum of 1.2 mg in 15 minutes.

The tablets should be dispensed in the original, unopened manufacturer's container and stored in the original brown bottle. Because sublingual NTG tablets are degraded by heat, moisture, and light, they should be stored in a cool, dry place, but not refrigerated. The bottle should be closed tightly after each opening. Safety caps should not be used, although patients should be cautioned to keep all medications out of the reach of children. The cotton plug sometimes is difficult to remove. Therefore, it should be discarded on initial receipt of the prescription and should not be replaced. Use of cotton other than that supplied by the manufacturer should be discouraged because NTG tablets are volatile and are adsorbed by household cotton. This results in a significant loss in tablet effectiveness. Expiration dating should be monitored closely, and tablets should be replaced immediately if they are exposed to excessive light, heat, moisture, or air. Once a container is opened, the tablets should be used for only a limited time—usually from 6 months to 1 year.[1]

ADRENERGIC BLOCKERS

Case 12-1, Question 11: Given J.P.'s active lifestyle and recent history of frequent anginal attacks, the medical team wishes to optimize chronic preventative therapy for chronic stable angina. J.P. currently is receiving metformin 500 mg bid, lisinopril 10 mg once daily, and hydrochlorothiazide 25 mg once daily. His current resting heart rate and BP are 78 beats/minute and 135/90 mm Hg, respectively. Is a β-blocker the best initial option for chronic stable angina in J.P.?

Options for chronic prevention of anginal episodes include β-blockers, CCBs, long-acting nitrates, and ranolazine. Current guidelines recommend that β-blockers should be administered before a nitrate or a CCB when long-term therapy is indicated.[1,2] β-Blockers are very effective at reducing anginal symptoms and ischemia, including silent myocardial ischemia.[1,2] β-Blockers also significantly increase exercise tolerance and time to ST-segment depression during exercise testing.[36] Several cohort and case–control studies have shown that β-blockers improve clinical outcomes, including reductions in mortality in patients with chronic stable angina or CAD.[52–56] In addition, evidence indicates that β-blockers may also slow the progression of atherosclerosis.[57] In a meta-analysis of clinical trials that compared the three classes of anti-ischemics, no differences in long-term mortality were noted. β-Blockers, however, were more effective in lowering the incidence of anginal episodes.[58] In addition, β-blockers clearly lower morbidity and mortality in patients with CAD[17,19] and HF.[36] Overall, the body of literature available supports the recommendation that all patients with angina should receive a β-blocker as initial therapy unless contraindicated.[59] J.P. at this time does not appear to have any contraindications to β-blocker therapy, and β-blocker therapy should be initiated.

Case 12-1, Question 12: How should therapy with a β-blocker be optimized in J.P.?

All patients receiving antianginal drugs should be monitored for frequency of angina attacks and SL NTG consumption. Traditionally, clinicians have monitored the reduction in resting heart rate and have progressively increased the β-blocker dose until the resting heart rate was 55 or 60 beats/minute.[36] J.P. currently has a heart rate of 78 beats/minute and preserved BP. If J.P. continues to have preserved BP and his heart rate remains above 55 to 60 beats/minute after the initiation of β-blocker therapy, a doubling of his

dose would be a reasonable increase, with close monitoring of heart rate and BP. Additional goals with β-blocker therapy include a maximum heart rate of 100 beats/minute or less with exercise. Resting heart rate <50 beats/minute may be acceptable, provided the patient is asymptomatic and heart block is not present. Variations in resting heart rate are normal and subject to the influence of the endogenous sympathetic nervous system and other exogenous factors, such as drugs, tobacco, and caffeine-containing beverages. β-Blockers with intrinsic sympathomimetic activity (eg, pindolol) will not reduce the resting heart rate as much as β-blockers lacking this activity.[35]

Exercise stress testing is probably the most accurate, but least practical, method of documenting the adequacy of β-blocker therapy. During an exercise tolerance test, a β-blocker should substantially increase the time J.P. walks before developing angina. There also may be a reduction in ST-segment depression during exercise, indicating less myocardial ischemia. The rate–pressure product probably will be markedly lower, reflecting a decrease in both heart rate and systolic wall tension.[34] An alternative to conducting a formal stress test is to repeat the physical activity that produced angina during this hospitalization, namely, walking a few flights of stairs.

Case 12-1, Question 13: Would the decision to use β-blockers initially in J.P. be altered if he had a history of reactive airway disease such as asthma or PAD?

Although all β-blockers are equally effective in the treatment of angina, the addition of reactive airway disease or PAD to J.P.'s medical history would pose several relative contraindications to the use of some β-blockers. The concern directly relates to the potential for β-blockers to worsen either bronchoconstriction in the case of asthma by blunting β_2 receptors or worsening vasoconstriction in the peripheral arteries, again, through blunting vasodilation through β_2-receptors. Although not absolute contraindications, the presence of

these disease states warrants careful monitoring of β-blocker therapy during initiation and titration.[34]

Cardioselective β-blockers, such as metoprolol, are often considered in patients with reactive airway disease or PAD with the hope that β_2-receptors will be unaffected. In one meta-analysis, cardioselective β-blockers were better tolerated than nonselective β-blockers in patients with asthma.[60] Cardioselective β-blockers also are less likely to inhibit β_2-mediated vasodilation in the peripheral arterioles. Therefore, cardioselective β-blockers are preferred over nonselective β-blockers for patients with PAD and Raynaud disease.[2,61]

Unfortunately, cardioselectivity is not an all-or-none response; instead, it is a dose-dependent phenomenon. As the dose is increased, cardioselectivity is lost. The dose at which cardioselectivity will be lost in any given patient cannot be predicted, and even a very small dose (eg, metoprolol 50–100 mg) could cause wheezing.[35,61] If β-blocker therapy is to be initiated in a patient with reactive airway disease or PAD, close monitoring for worsening of symptoms should occur and an alternative anti-ischemic medication should be used if symptoms worsen.

In the event that β-blocker therapy is not tolerated or considered too risky, initial therapy with a heart-rate–controlling CCB is the next best option, provided there is adequate heart rate and BP to tolerate therapy. In patients who already have low heart rate and/or marginal BP, ranolazine may be considered as an initial option. Long-acting nitrates are typically reserved for add-on therapy for reasons that will be subsequently discussed.[1]

Case 12-1, Question 14: J.P. is being discharged from the hospital today with prescriptions for SL NTG 0.4 mg tablets, metoprolol succinate 100 mg once daily, metformin 500 mg bid, and lisinopril 20 mg once daily, and education regarding diet and exercise. Is there anything else J.P. should receive for his chronic stable angina?

Antiplatelet therapy is a cornerstone in the management of a patient with atherosclerotic vascular disease. Antiplatelet therapy

reduces the incidence of CVD events such as MI, stroke, and death. Although newer antiplatelet options are available, aspirin is still the first-line choice for patients with atherosclerotic vascular disease because of well-established efficacy and cost-effectiveness.[1]

The mechanism of action for aspirin's antiplatelet effect is inhibition of cyclooxygenase (see Chapter 11, Thrombosis). By acetylating the active site of cyclooxygenase, aspirin blocks the formation of prostaglandin endoperoxides from arachidonic acid. This inhibits the formation of both thromboxane and prostacyclin. Thromboxane A_2 is a potent vasoconstrictor and facilitates further activation of platelets. Prostacyclin (PGI_2) counterbalances the effect of thromboxane A_2, because it is a potent inhibitor of platelet aggregation and a vasodilator.[62]

Although it has been theorized that higher doses of aspirin would produce a higher level of efficacy than low doses, all available literature indicates that low dosages of aspirin (75–325 mg/day) are as effective as higher dosages (625–1300 mg/day) in the treatment of patients with angina.[62] Conversely, as the aspirin dosage increases, the incidence of adverse effects, especially GI bleeding, increases. Therefore, current guidelines recommend a daily dosage of 75 to 162 mg orally for the prevention of MI and death in patients with CAD.[1] Given this information, J.P. should be advised to take aspirin at a dose of 81 mg/day to maintain efficacy but decrease the risk of adverse effects.

CASE 12-1, QUESTION 15: J.P. returns to the hospital with recurrent angina 8 weeks after he was discharged. He mentioned he stopped his metoprolol 36 hours ago when he forgot to get his prescriptions refilled. He is transported to the hospital emergency department for treatment of angina unresponsive to three NTG tablets. How could J.P.'s situation have been avoided?

The β-blocker withdrawal syndrome is a rebound phenomenon resulting from heightened β-receptor density and sensitivity (ie, upregulation) subsequent to receptor blockade. It places patients with CAD at high risk for adverse cardiovascular events, which may

include acute MI and sudden cardiac death. An “overshoot” in heart rate, as a consequence of sympathoadrenal activity from abrupt β-blocker withdrawal increases myocardial oxygen demand and platelet aggregation. Withdrawal syndromes may be less severe in patients taking β-blockers with partial agonist activity.[34–36]

If β-blockers are to be discontinued, a gradual tapering schedule (preferably for 1–2 weeks) should be used. Shorter periods for β-blocker withdrawal (eg, 2–3 days) have been proposed, although the optimal strategy for discontinuation is not known. Ensuring that β-blockers are tapered and that the patient is reasonably monitored for adverse events for the duration of the taper is imperative. Patients should limit physical activity throughout the β-blocker withdrawal period and seek prompt medical attention when angina symptoms become apparent. Patients should be warned not to precipitously discontinue their β-blockers. Failure to renew prescriptions and financial hardship are common reasons for abrupt discontinuation, and clinicians need to have sufficient professional rapport with patients to understand when patients encounter difficulties in obtaining medications.

LONG-ACTING NITRATES

Case 12-1, Question 16: J.P. recovers quickly and is discharged from the hospital after 48 hours. He does well during the next several months, but he is still bothered by occasional angina episodes, two to four times a week. The attacks usually are precipitated by strenuous work and are relieved by rest and two or three NTG tablets. The quality and location of the pain are unchanged, although the duration has increased by 1 or 2 minutes. He follows a low-cholesterol, no-added-salt diet. Physical examination is unchanged except for a 20-pound (9.07 kg) weight loss. Vital signs include the following: supine BP, 119/76 mm Hg; heart rate, 60 beats/minute; and respiratory rate, 12 breaths/minute. J.P.’s cardiologist elected to start a long-acting prophylactic nitrate (isosorbide mononitrate) as well as continuing his metoprolol succinate (100 mg daily), lisinopril (20 mg daily), aspirin (81 mg daily), and metformin (500 mg twice daily). Is a long-acting nitrate the best add-on option for J.P.’s chronic stable angina?

Long-acting nitrates occupy a key role in the prevention of angina of all types. The goals of therapy are to decrease the number, severity, and duration of J.P.'s anginal attacks. A CCB could be prescribed for J.P. instead of isosorbide mononitrate because he has no contraindications to this class of drugs. A CCB would have been a good alternative if his BP had remained elevated, but for now, J.P.'s BP and pulse are within the desired range. Nitrates can also affect BP but will likely do so to a lesser extent than CCBs. Because sublingual nitrates were well-tolerated by J.P., a long-acting nitrate would be acceptable. If a CCB is considered at this point, a DHP should be used because they have no effect on heart rate, unlike diltiazem or verapamil. Lastly, ranolazine would be an option for add-on therapy, especially if J.P. experiences any adverse hemodynamic effects from either a CCB or long-acting nitrate. Ultimately, the decision for additional therapy is based on the prescriber's personal choice and past experience, as well as the entire spectrum of the patient's disease complex.[63]

Case 12-1, Question 17: Will J.P. develop tolerance to the long-acting nitrate?

Although not completely understood, several mechanisms of nitrate tolerance have been proposed, including the increased production of catecholamines, plasma volume expansion, and activation of the renin–angiotensin–aldosterone system.[64]

All organic nitrates exhibit similar hemodynamic effects through a common pharmacologic mechanism; yet, the differing pharmacokinetic profiles of the nitrate delivery systems lead to a variation in the development of tolerance.[65] Short-acting formulations (eg, SL NTG, oral NTG spray, and SL isosorbide dinitrate) are not likely to induce tolerance given their rapid onset of action and short duration of effect. Oral nitrates and transdermal products, both having an extended duration of action, are likely to induce tolerance.

Intermittent application of transdermal NTG can limit tolerance development in patients with both chronic stable angina and HF. The

effects of continuous (24 hours/day) and intermittent (16 hours/day) transdermal NTG (10 mg/day) were compared in 12 males with chronic stable angina who also were being treated with β-blockers or CCB.[66] Nitrate efficacy was maintained with intermittent treatment and an 8-hour nitrate-free interval. Tolerance to the antianginal effects occurred, however, with continuous treatment. Twelve-hour intermittent patch therapy also prevents tolerance.[67] The minimal time necessary for a nitrate-free interval is unknown. Nitrate dosing schedules should be arranged to permit a nitrate-free interval during which time the patient may receive angina protection from β-blockers, CCBs, or ranolazine. Most often, this nitrate-free interval is arranged during the night because angina is more likely to occur during the workday. Patients with nocturnal or early morning angina should arrange their nitrate-free interval during the day.[68]

Despite the availability of nitrate preparations that can be dosed once or twice a day (isosorbide mononitrate), oral isosorbide dinitrate is still commonly used in a variety of settings for the treatment of angina. Isosorbide dinitrate needs to be dosed three times a day and presents a challenge in ensuring patients have a nitrate-free interval. If J.P. were to receive isosorbide dinitrate, he should take his oral nitrate at 7 AM, noon, and 5 PM because his exercise-induced angina is likely to occur during daylight hours. If he were to take isosorbide dinitrate on a more traditional three-times-a-day or every-8-hours schedule, he would be in danger of not having an adequate nitrate-free interval. Because long-acting nitrates must be dosed intermittently to avoid tolerance, metoprolol therapy will provide J.P. with continuous protection, even during the nitrate-free interval. Although J.P. uses a long-acting nitrate, he still will respond favorably to sublingual NTG. No evidence indicates that use of long-acting nitrates leads to resistance or tolerance to the effects of sublingual NTG.

Case 12-1, Question 18: Does isosorbide mononitrate offer any distinct advantages over other nitrate preparations for angina prophylaxis?

Isosorbide mononitrate is the primary metabolite of isosorbide dinitrate. In fact, most of the clinical activity of isosorbide dinitrate is because of the mononitrate. Therefore, both drugs share a similar pharmacology. Isosorbide mononitrate does not undergo first-pass metabolism and has no active metabolites. Its oral bioavailability is almost 100%, and its overall elimination half-life is about 5 hours.[65] Maximal serum concentrations are observed 30 to 60 minutes after a dose. To minimize the potential development of nitrate tolerance, isosorbide mononitrate should be used in a twice-daily, asymmetric dosing regimen in which the first dose is taken on awakening and the second dose about 7 hours later. Because of this unconventional dosing pattern and the availability of the extended-release product, which can be taken once a day, most use of isosorbide mononitrate is in the form of the extended-release preparation. Pharmacists must be sure to recognize the difference between these two products.

General precautions and adverse reactions for isosorbide mononitrate are similar to those for the other nitrates. Potential advantages for the clinical use of isosorbide mononitrate are less dosage fluctuation because of the absence of presystemic clearance and an effective once-daily or twice-daily dosing schedule, which could perhaps lead to improved patient adherence. Nevertheless, isosorbide dinitrate is effective clinically when administered two or three times a day and is a viable alternative.

Case 12-1, Question 19: J.P. likes the idea of using topical nitrates instead of an oral agent. Are the transdermal patches a viable alternative?

Transdermal NTG patches were originally designed to provide anti-ischemic protection with once-daily application. The concept of a compact, easy-to-apply transdermal NTG patch prompted pharmaceutical manufacturers to design a number of products, which the FDA subsequently approved based on plasma level data, not clinical efficacy studies. Subsequently, the shortcomings of plasma level data have become apparent and prompted numerous clinical efficacy studies.

Transdermal NTG therapy has been shown to increase exercise duration and maintain an anti-ischemic effect for 12 hours after patch application. These beneficial responses remained consistent throughout 30 days of therapy. No significant nitrate tolerance or rebound was noted when the patch was applied for not more than 12 of 24 hours.[65]

Although the various patches use different pharmaceutical delivery systems, clear-cut advantages of one over another are not apparent. Despite variations in surface area and NTG content, the most important common denominator of the transdermal NTG systems is the amount of drug released per hour expressed as the release rate (eg, 0.2 mg/hour). Each product label includes this information. Low dosages (0.2–0.4 mg/hour) may not produce sufficient plasma and tissue concentrations to produce a clinically significant effect[3]; however, it is still recommended to start with a low-dose patch and titrate upward as needed. Because the skin is the major factor influencing NTG absorption rate, product release characteristics do not favor one system over another. Contact dermatitis has been reported with the transdermal patches. Patient instructions are included with the patches and should be reviewed with the patient, emphasizing the appropriate time for application of the patch, removal of the patch, as well as the appropriate sites on the body where the patch should be placed.

CALCIUM CHANNEL BLOCKERS

CASE 12-2

QUESTION 1: B.N., a 56-year-old male, has just undergone cardiac catheterization, which showed two-vessel CAD with obstructions of 55% and 65% in the right coronary and circumflex coronary arteries, respectively. Before catheterization, he had a 2- to 3-month history of exertional angina for which his primary care physician prescribed sublingual NTG tablets (0.4 mg) and oral isosorbide mononitrate (60 mg once daily). B.N. discontinued the use of isosorbide mononitrate after a few weeks because of intolerable headaches. His medical history includes asthma, hypertension, and hyperlipidemia. Currently, his other medications include losartan 100 mg once daily, fluticasone inhaler two puffs twice daily, albuterol inhaler two puffs as needed, aspirin 81 mg daily,

and atorvastatin 20 mg daily. Current vital signs include a resting heart rate of 75 beats/minute, BP of 125/80 mm Hg, and respiratory rate of 14 breaths/minute. His physician begins antianginal therapy with oral diltiazem 120 mg once daily.

Is this a good option for B.N. and his chronic stable angina?

CCBs are effective in both vasospastic and classic exertional angina. These drugs relieve vasospasm of the large coronary arteries and, as a result, are effective in treating Prinzmetal variant angina. Their beneficial effect in chronic stable (effort-induced) angina is the result of multiple factors. Their vasodilatory effects in the coronary circulation increase myocardial oxygen supply, whereas dilation of the peripheral arterioles leads to a reduction in myocardial oxygen demand. Because coronary vasospasm can occur at the site of an atherosclerotic plaque, a CCB is particularly useful in patients who have a vasospastic component to their angina.[40,69]

Although β-blockers are considered the drugs of choice when instituting antianginal therapy,[1] data indicate that CCB may also be a reasonable first-line choice. CCBs and β-blockers appear to provide equivalent efficacy in head-to-head trials of chronic stable angina.[70–72] In addition, the available head-to-head trials with sufficient numbers also suggest that CCBs and β-blockers produce similar effects on cardiovascular outcomes and mortality in patients with chronic stable angina.[40,73] In addition, several trials in the setting of hypertension with CAD have demonstrated that CCBs can produce meaningful reductions in mortality.[74–77] It would appear that either a CCB or a β-blocker may be considered relatively equal options and initial therapy for chronic stable angina. The selection of a particular class will likely be dictated by patient characteristics.

In the case of B.N., his asthma may be worsened by the addition of a β-blocker. Although a cardioselective β-blocker could be tried to see if B.N. could tolerate it, a heart rate–lowering CCB is a good alternative to a β-blocker for the treatment of angina in this situation. The choice of a CCB as initial therapy in this patient is appropriate because of B.N.’s previous intolerance to nitrates and because nitrate therapy requires a nitrate-free period.[1]

Given B.N.'s current heart rate and BP, the selection of a heart rate–lowering CCB seems most appropriate. However, the distinct pharmacologic and adverse event profiles of the various classes may dictate agent selection from patient to patient. Some side effects of CCBs reflect an extension of their hemodynamic and electrophysiologic profiles and, therefore, are predictable (**Table 12-6**). DHP-induced hypotension and dizziness occur in ~15% of patients. Patients also may report light-headedness, facial flushing, headache, and nausea. Swelling of the lower legs and ankles (peripheral edema) is related to the potent peripheral vasodilating effects of these agents. The non-DHPs, verapamil and diltiazem, have similar side effect profiles, although diltiazem appears to be better tolerated. The lower incidence of side effects reported with diltiazem, compared with verapamil, may reflect a true difference or, perhaps, less aggressive dosing regimens. Both drugs can cause sinus bradycardia and worsen already existing conduction defects and heart block.[40,69] Neither should be used in patients with sick sinus syndrome or advanced degrees of heart block unless a functioning ventricular pacemaker is present. Patients should be monitored for signs of worsening HF, such as SOB, weight gain, and peripheral edema. Verapamil-induced constipation can be particularly troublesome to the elderly.[3,40]

Table 12-6
Calcium Channel Blocker Hemodynamic and Electrophysiologic Profile

Effect	Dihydropyridine Derivatives[a]	Diltiazem	Verapamil
Peripheral vasodilation[b]	+++	++	++
Coronary vasodilation[b]	+++	+++	++
Negative inotropes[c]	±	++	+++
AV node suppression[c]	±	+	++
Heart rate	Increase (reflex)	Decrease or unchanged	Decrease or unchanged
Pharmacokinetics[d]			
Dosing[e]			
Side Effects			
Nausea, vomiting	+ (most)	+/1	±
Constipation	Not observed	±	+
Hypotension, dizziness[f]	++	+	+
Flushing, headache	++	+	+
Bradycardia, HF symptoms	±	+	++
Reflex tachycardia, angina	+[f]	Not observed	Not observed
Peripheral edema	+	±	±

[a]Dihydropyridine derivatives that are U.S. Food and Drug Administration approved for angina: amlodipine (Norvasc), nicardipine (Cardene), and nifedipine (Adalat, Procardia).

[b]Peripheral and coronary vasodilation helpful for angina, hypertension, and possibly HF, but peripheral dilation is the basis for side effects of flushing, headache, and hypotension.

[c]AV node suppression is helpful for controlling supraventricular arrhythmias, but this property plus the negative inotropic effect may worsen HF. Nifedipine has less negative inotropic effect than verapamil and diltiazem but still may worsen HF. Amlodipine may have the least negative inotropic effect.

[d]All have poor bioavailability owing to high first-pass metabolism and all are eliminated primarily by hepatic metabolism; intradivisional and interindividual variability in bioavailability and metabolism is extensive. Diltiazem, nifedipine, nicardipine, and verapamil have a short half-life (<5 hours) requiring frequent dosing or use of sustained-release products. Amlodipine, isradipine (8 hours), and felodipine (10–20 hours) have longer half-lives.

[e]See Table 12-5.

[f]Hypotension and reflex tachycardia most with immediate-release nifedipine, occasional with immediate-release diltiazem and verapamil, minimal with sustained-release products or intrinsically long-acting agents.

Sources: Cooper-DeHoff RM, Chang SW, Pepine CJ. Calcium antagonists in the treatment of coronary artery disease. *Curr Opin Pharmacol*. 2013;13:301–308. Opie LH. Calcium channel blockers. In: Opie LH, Gersh BJ, eds. *Drugs for the Heart*. 8th ed. Elsevier Health Sciences; 2013.

Appreciation for the individual side effect profiles helps determine preference for one CCB over another. B.N. is not likely to experience

major side effects with either verapamil or diltiazem.

Case 12-2, Question 2: On questioning, B.N. does not report any previous adverse events or tolerance issues with an ACE inhibitor. Is an ARB appropriate to use in B.N. or should he be switched to an ACE inhibitor for his CAD?

As discussed, the totality of available evidence supports the role of ACE inhibitors in reducing total mortality, cardiovascular mortality, nonfatal MI, and stroke in patients with stable IHD and preserved ventricular function. Although in theory ARBs should produce the same beneficial effects as ACE inhibitors in patients with atherosclerosis, there are far fewer clinical trials with ARBs. The best supporting evidence comes from the TRANSCEND and ONTARGET trials, both of which suggest ARBs produce similar benefits as ACE inhibitors in preventing CVD events.[77,78] Based on these trials, it would be reasonable to continue ARB therapy in B.N. at this time given he has demonstrated the ability to tolerate the medication. It would not be unreasonable though to discuss with B.N. the possibility of switching to an ACE inhibitor given the substantial body of evidence that exists for patients with CAD. The combination of an ACE inhibitor and ARB does not offer any increased benefit but does increase the risk of hyperkalemia and renal insufficiency.[78]

Case 12-2, Question 3: Six months later, B.N. returns to see his physician. His current therapy consists of SL NTG 0.4 mg tablets, losartan 100 mg once daily, fluticasone inhaler two puffs twice daily, albuterol inhaler two puffs as needed, aspirin 81 mg daily, atorvastatin 20 mg daily, and diltiazem 180 mg once daily. Current vitals include a resting heart rate of 55 beats/minute, BP of 115/65 mm Hg, and respiratory rate of 10 breaths/minute. B.N. states he still is having roughly three to four anginal attacks per week when he exerts himself doing yard work. Would ranolazine be a therapeutic option for his chronic stable angina at this time?

Although higher doses of diltiazem might be attempted in B.N., his current heart rate and BP would likely prevent further titrating of therapy. β-Blocker therapy is not a good option because of the potential reduction in heart rate and asthma. Thus, ranolazine

represents a good option for B.N. at this time because of the absence of heart rate and BP-lowering effects with ranolazine. Several large, randomized studies with ranolazine have been conducted, all demonstrating its effectiveness at reducing ischemia and angina when added to existing therapy. The Monotherapy Assessment of Ranolazine in Stable Angina (MARISA) trial found that compared to placebo, ranolazine significantly increased exercise duration, time to onset of angina, and 1-mm ST-segment depression during exercise treadmill testing.[79] Similar results were seen in the Combination Assessment of Ranolazine in Stable Angina (CARISA) trial where ranolazine when added to antianginal monotherapy.[80] The Efficacy of Ranolazine in Chronic Angina (ERICA) trial assessed the effects of ranolazine added to amlodipine 10 mg/day. Patients receiving 1000 mg/day of ranolazine had a significant reduction in both the number of weekly anginal attacks as well as the number of SL NTG tablets used when compared to placebo.[81] A reduction in the frequency of angina was also seen in patients with CAD and diabetes mellitus when ranolazine was added in the Type 2 Diabetes Evaluation of Ranolazine in Subjects with Chronic Stable Angina (TERISA) study.[82] Ranolazine was well-tolerated in all four of these trials with the most common side effects being dizziness, constipation, nausea, and headache. The incidence of adverse effects increased with increasing doses. No other significant adverse effects were noted, although it is important to note that the duration of these trials was limited.[41]

Information regarding the safety of ranolazine in patients with longer drug exposure came from the Ranolazine Open Label Experience (ROLE) program,[83] which followed patients from the MARISA and CARISA trials who continued in an open-label extension program. A total of 746 patients initially entered the 6-year run-on safety program. At the time of publication, the mean duration of therapy was 2.82 years, with 23.3% of patients discontinuing therapy. One-half of the withdrawals were because of adverse events, but the incidence of common adverse effects did not seem to change from that seen in the randomized portions of the clinical

trials. Mortality rates at both 1 year (2.8%) and 2 years (5.6%) indicate no adverse risk of ranolazine on overall mortality.

The Metabolic Efficiency with Ranolazine for Less Ischemia in Non–ST-Elevation Acute Coronary Syndrome (MERLIN)-TIMI 36 trial[84] randomly assigned patients to ranolazine or placebo in the setting of ACS. The incidence of recurrent ischemia was significantly reduced with ranolazine providing additional support for the efficacy of ranolazine in treating chronic stable angina. Although ranolazine appeared to offer no benefit in the setting of ACS, significant long-term safety data were seen in the trial. Importantly, the risk of mortality, sudden cardiac death, or symptomatic arrhythmias was not increased with ranolazine versus placebo. In fact, the incidence of arrhythmias in the first 7 days, as documented by Holter monitor, was significantly lower with ranolazine than with placebo.[85] This was an important finding given ranolazine produces a dose-dependent increase in the QT interval.[15,41] As QT prolongation activity has been associated with proarrhythmia in other medications, results from the MERLIN trial are reassuring that ranolazine appears to be safe to use for chronic treatment of patients with stable angina.

B.N. is at goal heart rate, and his BP is well controlled on his current regimen, but he continues to have anginal symptoms. Given the demonstrated efficacy in relieving anginal symptoms, as well as the safety profile in a patient like B.N., ranolazine would be an excellent option for him for additional angina control.

Case 12-2, Question 4: How should ranolazine be dosed in B.N.?

Ranolazine is marketed as an extended-release tablet formulation that should be dosed twice daily. Maximal plasma concentrations are observed 4 to 6 hours after administration of the extended-release formulation with a terminal half-life of 7 hours. With twice-daily dosing of the extended-release preparation, a more favorable peak-to-trough fluctuation of 1.6 is observed.[41] Steady state is typically reached within 3 days and oral bioavailability is 30% to 55%. Ranolazine is primarily metabolized by the liver through CYP3A4

(70%–85%) and CYP2D6 (10%–15%). Ranolazine also is a substrate for P-glycoprotein.[15,41] Patients should initially be started at an oral dose of 500 mg twice daily, which can be titrated up to a maximal dose of 1000 mg twice daily.[86]

Although ranolazine is an option in the treatment of chronic stable angina, careful patient selection is required for the drug to be used safely and effectively.[86] **Table 12-7** summarizes significant issues, which should be evaluated when the drug is being considered for a patient. For B.N., the main issue is the drug–drug interaction with diltiazem, and the maximum dose of ranolazine that should be used in patients receiving diltiazem is 500 mg twice daily. B.N. should be monitored closely for possible increased adverse effects with ranolazine.

Table 12-7
Considerations for the Use of Ranolazine in Patients With Chronic Stable Angina

Clinical Issue	Recommended Management Strategy
Renal insufficiency	Ranolazine plasma levels may increase up to 50%. Caution with dose titration to maximal recommended dose.
Hepatic insufficiency	Ranolazine is contraindicated in patients with clinically significant hepatic impairment.
Drug Interactions: Effects on Ranolazine	
Strong CYP3A4 inhibitors	Plasma concentrations of ranolazine are significantly elevated when combined with potent inhibitors of CYP3A4. Ranolazine is contraindicated in patients receiving strong CYP3A4 inhibitors (ketoconazole, clarithromycin, nelfinavir, etc).
Moderate CYP3A4 inhibitors	Limit the dose of ranolazine to 500 mg twice daily in patients receiving moderate inhibitors of CYP3A4 (diltiazem, verapamil, erythromycin, fluconazole, etc).
CYP3A4 inducers	Coadministration of ranolazine with CYP3A4 inducers is contraindicated and should be avoided.
P-glycoprotein inhibitors	Caution should be exercised when coadministering ranolazine with P-glycoprotein inhibitors, and the dose of ranolazine may need to be lowered based on clinical response.
Drug Interactions: Effects on Other Medications	

Simvastatin	Plasma levels of simvastatin are increased twofold with coadministration with ranolazine through CYP3A4 inhibition by ranolazine; limit simvastatin dose of 20 mg daily when used with ranolazine; closely monitor for adverse effects (eg, myositis) from simvastatin.
Digoxin	Ranolazine coadministration increases plasma concentrations of digoxin by 1.5 times. Adjust dose of digoxin accordingly to maintain desired therapeutic level and response.
Metformin	Limit the dose of metformin to 1700 mg daily when coadministered with ranolazine 1000 mg twice daily.
CYP2D6 substrates	Ranolazine can inhibit the activity of CYP2D6, and plasma concentrations of 2D6 substrates (β-blockers, tricyclic antidepressants, antipsychotics) may be increased and lower doses of these agents may be required.
QT prolongation	Caution is recommended if the patient is on other QT-prolonging drugs, or has QT prolongation as baseline.

CASE 12-3

QUESTION 1: E.R. is a 58-year-old female with a history of chronic stable angina for the last several years that has been managed primarily with medical therapy. Her current medications include oral isosorbide mononitrate 120 mg daily, oral metoprolol succinate 200 mg daily, ranolazine 1000 mg twice daily, fluticasone two puffs bid, albuterol two puffs as needed, NTG spray 0.4 mg as needed for chest pain, and enteric-coated aspirin 81 mg/day. Today she returns to your pharmacy to obtain refills of her medications with her 64-year-old brother who wants to know if he should be taking an aspirin a day to prevent heart disease. His only medical history consists of hypertension for which he is taking oral hydrochlorothiazide 25 mg/day.

Is primary prevention of CAD with aspirin appropriate for E.R.'s brother?

The question of whether aspirin is valuable in the primary prevention of cardiovascular events has been debated for more than 30 years. The absolute risk–benefit ratio for aspirin in primary prevention will depend on the overall absolute risk of vascular

ischemic events. Several meta-analyses suggest that any benefit for aspirin in reducing ischemic events is offset by an increase in bleeding, resulting in no net clinical benefit.[87–90]

The 2019 ACC/AHA guideline on primary prevention of CVD provides contemporary recommendations for the use of ASA in primary prevention, incorporating more recent evidence.[91] Patients who are between the ages of 40 to 70 years, who are at high risk for atherosclerotic cardiovascular disease (ASCVD) but do not have a high bleeding risk, can be considered for the use of ASA for primary prevention. Importantly, this is a class 2b recommendation indicating that the literature supporting this recommendation is mixed. Because E.R.'s brother is 64 years old, it is appropriate for him to consider the use of aspirin for primary prevention, provided he is found to be at high risk for ASCVD and does not carry a high bleed risk. Recognizing the existing controversy surrounding the use of aspirin for primary prevention, a thorough review of the potential risk and benefits should take place with E.R.'s brother so that he may make the most informed decision possible.

CASE 12-3

QUESTION 2: E.R. buys a bottle of OTC ibuprofen. On further questioning, you learn that E.R. suffers from occasional back and knee pain and uses ibuprofen three to five times a week for pain relief.

How should E.R. be educated regarding the use of ibuprofen and aspirin concomitantly?

In 2006, the FDA released a warning statement on the concomitant use of both aspirin and ibuprofen. The impetus for the statement was the growing recognition that nonsteroidal anti-inflammatory drugs (NSAIDs), in particular ibuprofen, may attenuate the antiplatelet effects of low-dose aspirin. This FDA warning was then followed by an updated scientific statement, from the AHA.[92] The mechanism of this interaction is that both aspirin and nonselective NSAIDs bind to the same acetylation sites of the cyclooxygenase enzyme. Although aspirin does this in a

nonreversible fashion, binding by an NSAID occurs in a reversible fashion. If an NSAID, such as ibuprofen, is present, aspirin will be unable to bind to its site of action and will be rapidly cleared from the plasma. The result is the patient will not receive the antiplatelet benefit of aspirin.

E.R. should be counseled on the consequences of the interaction between her aspirin and ibuprofen. Additionally, if she can avoid or at least minimize (both dose and duration) the use of ibuprofen, the effect on her cardiovascular health would be optimized. If occasional use of ibuprofen cannot be avoided, it should be administered to minimize the potential for interacting with her aspirin. This would include taking ibuprofen at least 2 hours after her daily dose of aspirin, as well as taking her daily aspirin dose at least 8 hours after the last dose of ibuprofen. Although similar concerns exist for other nonselective NSAIDs (naproxen, diclofenac), no formal recommendations exist on how to manage concomitant use of these agents with aspirin.[92] Beyond the potential drug–drug interaction with aspirin therapy, there has emerged a large body of evidence that the use of NSAIDs in patients with underlying CVD may increase the risk of major adverse cardiovascular events. Although the underlying mechanisms remain to be determined, clinicians should minimize the use of NSAIDs if possible in patients with underlying CVD.[93]

REVASCULARIZATION

Percutaneous Coronary Intervention

Case 12-4, Question 1: Nine months later, E.R. returns to her cardiologist stating that her chronic angina has been worsening. She is experiencing chest pain more frequently and much sooner when she does any type of physical activity. Her current medications are the same as discussed previously, and it is felt that her medical management has been optimized as much as possible. After discussions with her cardiologist, she elects to undergo revascularization with PCI for symptom relief. What is the current standard for prevention of acute complications during PCI?

PCI, also known as angioplasty, involves the percutaneous insertion of a balloon catheter into the femoral or brachial artery. The catheter is advanced up the aorta and into the coronary arteries at the coronary sinus. PCI initially involved the inflation of a catheter-borne balloon that mechanically dilated a coronary artery obstruction through arterial intimal disruption, plaque fissuring, and stretching of the arterial wall. Balloon inflations were repeated until the plaque was compressed and coronary blood flow resumed. Since then, alternative devices have been developed, including rotational blades designed to remove atheromatous material, lasers to ablate plaques, and intracoronary stents that are designed to maintain the patency of the vessel after it is reopened.[94] Stents can be of the bare-metal (BMS) variety or contain a drug impregnated on the surface of the stent to prevent restenosis (DES). It is estimated that more than 1,265,000 PCI procedures are performed in the United States each year. An overwhelming majority of these procedures involve placement of a BMS or DES (**Fig. 12-5**). PCI is indicated in patients with single-vessel or multivessel disease and who are either symptomatic or asymptomatic.[20,94,95]

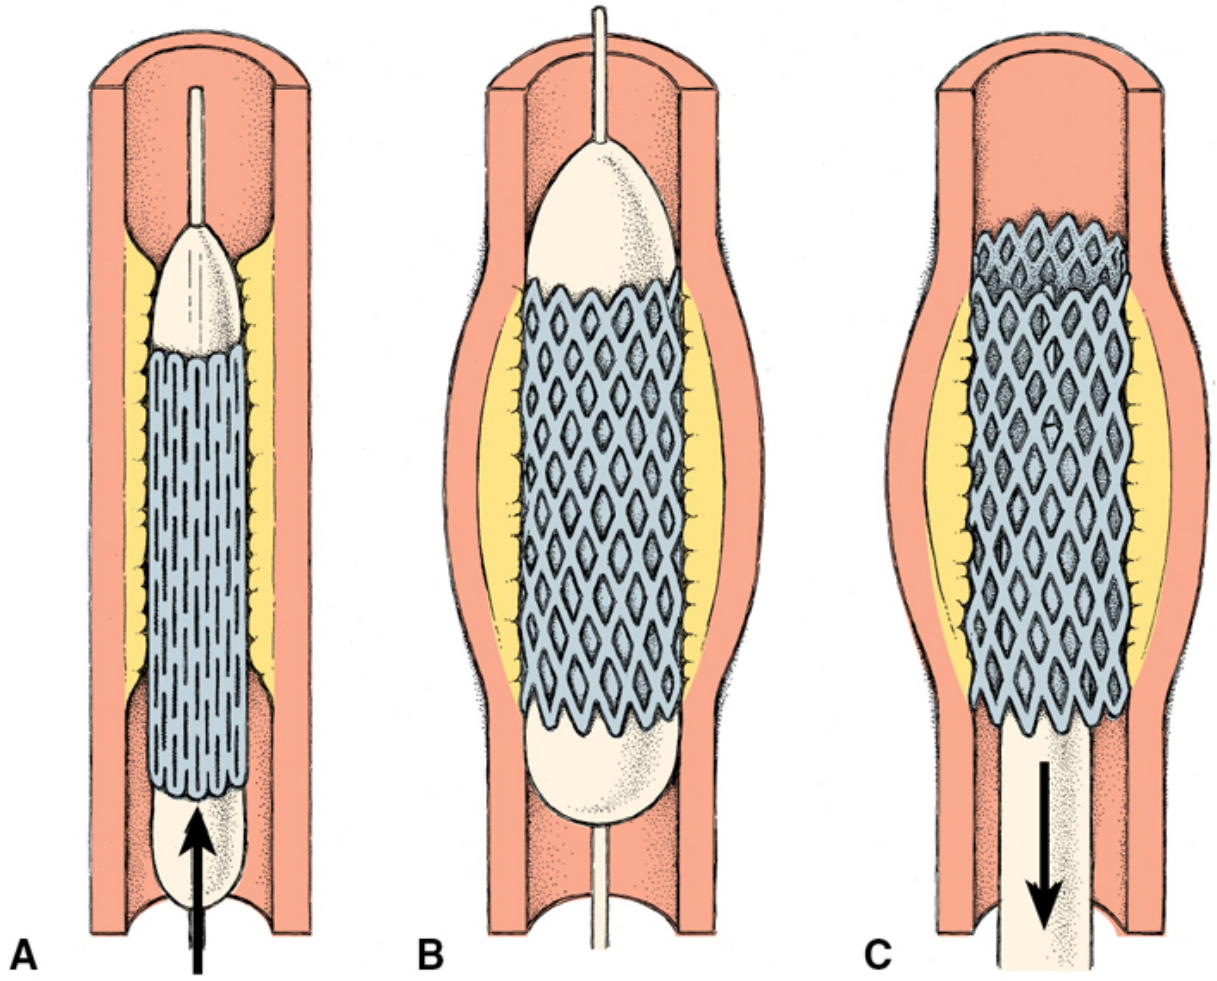

Figure 12-5 Vascular stent. A, A balloon catheter positions the stent at the site of arterial stenosis. B, Inflation of the balloon dilates the artery and expands the stent. C, The balloon is collapsed and withdrawn, leaving the expanded stent in position. (Illustration by Neil O. Hardy, Westpoint, CT.)

Because of mechanical disruption of the atherosclerotic plaques and exposure of plaque contents to the bloodstream during PCI, potent antiplatelet and antithrombotic strategies are needed to prevent acute thrombotic events such as MI and death. Current strategies in patients undergoing elective PCI involve the administration of aspirin, a $P2Y_{12}$ antagonist (clopidogrel, prasugrel, or ticagrelor), an antithrombin agent, and occasionally a glycoprotein (GP) IIb/IIIa receptor antagonist in selected patients. Although

ticagrelor and prasugrel represent alternatives to clopidogrel in patients undergoing PCI, current ACC/AHA guidelines recommend their use only in patients undergoing PCI in the setting of ACS. In patients not taking aspirin on a daily basis, 300 to 325 mg of aspirin should be given at least 2 hours before the procedure. Patients currently on daily aspirin therapy should receive 75 to 325 mg of aspirin before PCI is performed. A 600-mg loading dose of clopidogrel on or before the time of the procedure is currently recommended, producing an antiplatelet action within 2 hours.[16,17,20,95] Adequate antithrombin therapy such as unfractionated heparin, the low-molecular-weight heparin enoxaparin, or the direct thrombin inhibitor bivalirudin should be used in patients having elective PCI[20,95] (see Chapter 13, Acute Coronary Syndrome).

Case 12-4, Question 2: E.R. undergoes PCI plus placement of a DES to address a 75% lesion in her proximal left circumflex artery. What advantages and disadvantages are there in the decision to place a DES versus a BMS?

The overall success of any procedure is directly related to the experience of the operator, patient factors (such as LV function or number of vessels treated), and the equipment used. In patients receiving balloon angioplasty alone (without stent placement), repeat revascularization procedures (either repeat angioplasty or surgery) may be required in as many as 32% to 40% of cases because of lesion recurrence at the angioplasty site. The process is known as restenosis.[94] Many pharmacologic strategies have been studied in an attempt to reduce the risk of restenosis. The outcome with most methods has been disappointing. The only strategy that has been associated with a decrease in restenosis is the use of intraluminal stents.[94] Stents are essentially metal scaffolding devices placed into the vessel after balloon inflation has taken place. They provide a physical barrier to the recurrence of a significant stenosis at the site. One of the early drawbacks of the use of stents was the need for complicated antithrombotic regimens, including aspirin, heparin, dipyridamole, and warfarin, to prevent in-stent thrombosis. DAPT—a

combination of a $P2Y_{12}$ antagonist and aspirin—is effective at reducing in-stent thrombosis and is now recommended for use after stent placement.[20,95] The duration of DAPT will depend on the type of stent used as well as other clinical characteristics of the patient.

Recently, stents that elude antiproliferative agents such as sirolimus, paclitaxel, zotarolimus, or everolimus have been shown in clinical trials to reduce the incidence of restenosis compared with BMS.[96] Restenosis rates in clinical trials with these DES were in the single-digit range, as compared to 15% to 20% with traditional BMS. Soon after their introduction to the U.S. market, DES use grew to the point that >90% of stent use was DES. This trend abruptly halted in the fall of 2006 when several reports indicated a higher-than-expected incidence of stent thrombosis a year or more after DES placement. Although late stent thrombosis had previously been reported with BMS usage, the incidence was rare.[20] Shortly after these initial reports, an explosion of scientific literature emerged on the topic. Delayed endothelialization is seen with DES compared with BMS. After placement of an intracoronary stent, a healing process typically occurs resulting in growth of a protective layer of endothelial cells over the stent surface, removing the stent surface from blood exposure and drastically reducing the stimulus for thrombosis. In the case of DES coated with paclitaxel, sirolimus, or everolimus, cellular growth may be inhibited, significantly impairing endothelialization of the stent surface. In a small number of patients, endothelialization does not seem to occur at all. In this scenario, the stent structure remains continually exposed to flowing blood and is a potent stimulus for thrombosis.[97] More recent advances in percutaneous interventions and stent technology though have largely eliminated many concerns regarding late stent thrombosis, and in the setting of elective PCI shorter durations of intense antiplatelet therapy is needed to prevent thrombotic complications.[44]

One critical issue that had been identified as a cause of late stent thrombosis with DES is the premature discontinuation of DAPT. As such, consideration of whether the patient is likely to comply with aspirin and $P2Y_{12}$ antagonist therapy or afford such therapy based

on insurance status has become a significant factor in the decision process between using a BMS or DES. Previous recommendations called for varying durations of combined therapy, depending on the type of stent used. Because of the recognition of a delayed healing response to DES, current guidelines recommend at least 1 year of DAPT in patients receiving a DES if patients are not at an elevated risk of bleeding. For BMS placement, DAPT should continue for a minimum of 1 month, and up to 1 year ideally, but this extended duration is not as critical as it is in the setting of DES placement. After PCI, it is reasonable to use aspirin 81 mg daily rather than higher doses.[20] The dose of clopidogrel should be 75 mg/day.[20,95]

CASE 12-4, QUESTION 3: Would revascularization therapy with coronary artery bypass grafting have been a better option for E.R. than PCI and stent placement?

Coronary artery bypass grafting is a complicated surgical procedure during which an atherosclerotic vessel is bypassed using either a patient's saphenous vein or internal mammary artery (IMA; **Fig. 12-6**). The graft (ie, the saphenous vein or IMA) then allows blood to flow past the obstruction in the native vessel. The goals of antianginal therapy, whether medical (pharmacologic) or revascularization, remain unchanged: (a) to prolong life, (b) to prevent MI, and (c) to improve the quality of life.

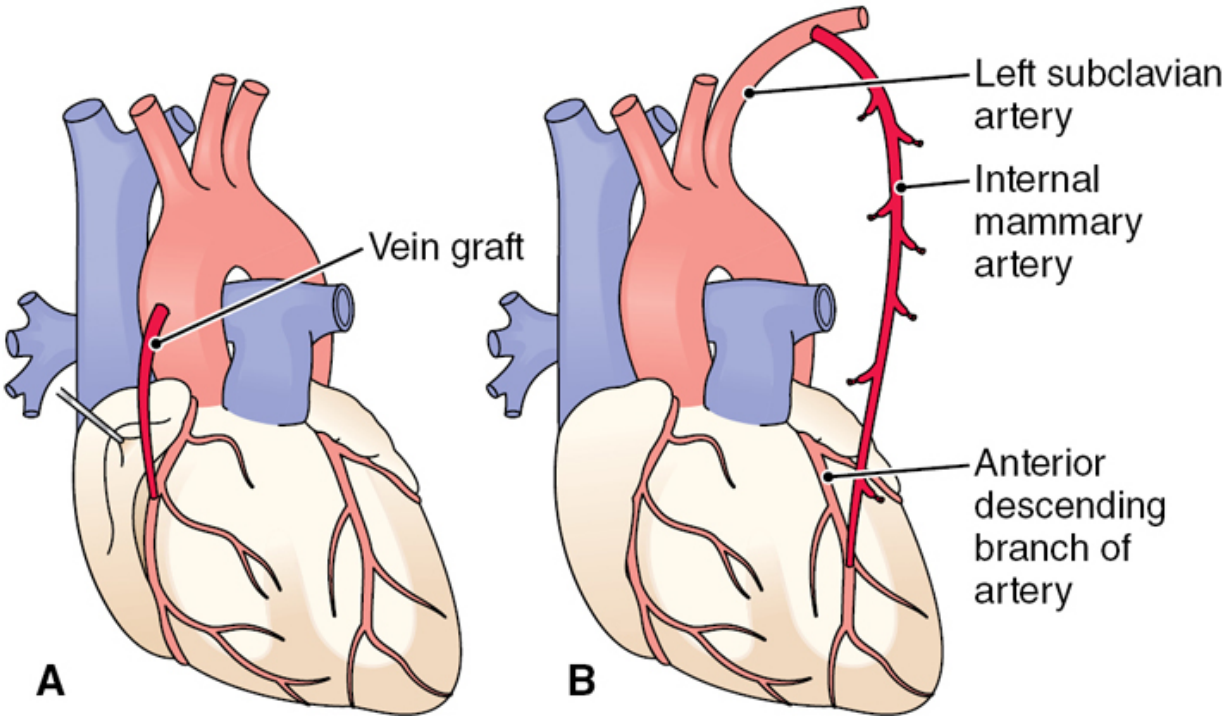

Figure 12-6 Coronary artery bypass graft (CABG). A, A segment of the saphenous vein carries blood from the aorta to a part of the right coronary artery that is distal to an occlusion. B, The mammary artery is used to bypass an obstruction in the left anterior descending (LAD) coronary artery. (Reprinted with permission from Cohen BJ. *Medical Terminology: An Illustrated Guide*. 7th ed. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2014.)

The outcomes of medical therapy, PCI, and revascularization with CABG have been compared, and current guidelines are available.[1,21] When compared with medical treatment in patients who would not be considered high risk, PCI in general offers no improvement in the long-term incidence of MI or cardiovascular death, but significantly reduces symptoms.[1] Because of her escalating symptoms on triple-drug therapy, the choice of PCI for E.R. is justified.

Certain subgroups of patient at high risk clearly have an improved outcome with CABG. These include (a) patients with significant left main coronary disease; (b) patients who have three-vessel disease, especially with LV dysfunction; (c) patients with two-vessel disease with a significant proximal LAD lesion; (d) patients who have

survived sudden cardiac death; and (e) patients who are refractory to medical treatment. In patients who do not meet these criteria, either medical treatment or PCI is a viable option.[1,20] Because E.R. does not fall into one of these categories, PCI is preferable owing to the less-invasive nature of the procedure and the equivalent outcomes that are seen. These results were recently confirmed in the Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation (COURAGE) trial.[43] Patients with CAD were randomly assigned to aggressive medical treatment with optimization of medical therapy and risk factors, or aggressive medical treatment plus PCI. During a 4.6-year period, no significant difference was noted between the groups in cardiovascular outcomes (death, MI, stroke, hospitalization for ACS). The only difference noted was better control of anginal symptoms early on with PCI, but that difference was no longer significant at the end of the study. These results highlight the crucial role of optimizing medical therapy (including diet, lifestyle changes, risk factor modification) for patients with CAD, regardless of whether revascularization is performed.[1]

Case 12-4, Question 4: E.R. undergoes PCI plus stent placement and returns to your pharmacy to have a new prescription filled. The prescription calls for clopidogrel at a dose of 150 mg once a day for 1 week, then 75 mg a day thereafter with 11 monthly refills. You have not seen clopidogrel dosed in such a manner. What is the rationale for the higher dose, and is there evidence to support its use?

Clopidogrel, a thienopyridine, inhibits platelet function as a noncompetitive antagonist of the $P2Y_{12}$ platelet adenosine diphosphate receptor. Clopidogrel is dosed at 75 mg daily, and this dose has been demonstrated to be effective and safe as monotherapy, or as a component of DAPT with aspirin, in a wide variety of settings for patients with CAD.[98] Despite proven efficacy, patients continue to experience clinical events while receiving clopidogrel.[99] It is now understood that clopidogrel does not produce a consistent antiplatelet response in many patients.[100]

Although the term clopidogrel resistance was first used to describe patients who do not have the expected antiplatelet response to standard doses of clopidogrel, a better term to describe this phenomenon is clopidogrel nonresponsiveness. Alternatively, the phrase *high on-treatment platelet reactivity* is also used commonly in the literature, especially when characterizing the clinical consequences of decreased antiplatelet response.[100] The presence of high on-treatment platelet reactivity in patients who have undergone PCI has been linked to a higher rate of stent thrombosis, MI, repeat revascularization, and death. This link has been observed in both patients with stable CAD undergoing elective PCI and patients with ACS. Although nonresponsiveness identifies an elevated risk for ischemic events, not all patients with identified clopidogrel nonresponsiveness necessarily go on to have recurrent events.[99]

There is a lack of consistency of how clopidogrel nonresponsiveness is defined. It may be defined as the presence of a recurrent ischemic event while on therapy. But, thrombosis is a complex interplay of many different factors, and recurrent clinical events do not necessarily imply a lack of antiplatelet effect. The identification of a lack of the expected biologic effect on platelet function is a more appropriate definition to work with. However, there are multiple tests available to assess the antiplatelet activity of clopidogrel (and other antiplatelet agents), and it is unclear which assay correlates best with clinical outcome and would be preferred to assess clopidogrel nonresponsiveness.[101,102] Because of the variability in available platelet function tests, as well as definitions of nonresponsiveness, estimates for the incidence of clopidogrel nonresponsiveness range anywhere from 5% to 44%.[100] **Table 12-8** lists some of the available laboratory testing modalities for antiplatelet agents, their pros and cons, as well as previously identified levels of high on-treatment platelet reactivity.[103]

Table 12-8
Commonly Used Platelet Function Tests for Assessment of

Antiplatelet Effects

Test	Pros	Cons	Monitoring Key Points
Turbidimetric aggregometry, commonly referred to as light transmission aggregometry	Historical gold standard	Large blood volume Expensive Poor reproducibility Time-consuming Technical complexity	Whole blood assay Can be used for multiple antiplatelet agents with variable reagents
VASP phosphorylation	Whole blood assay Small blood volume needed	Technical complexity Expensive Requires a flow cytometer	Specific for thienopyridines Cutoff for antiplatelet nonresponsiveness PRI >50%
VerifyNow	True point-of-care assay Large number of patients studied Whole blood assay Simple and rapid	Cartridge cost Limited ranges for hematocrit and platelet count	Can assess multiple antiplatelet agents Cutoff for antiplatelet nonresponsiveness PRU >235–240
Thromboelastography	Whole blood assay Point of care	Limited clinical studies Substantial pipetting of reagents	Can assess multiple antiplatelet agents

PRI, platelet reactivity index; PRU, platelet reaction units; VASP, vasodilator-stimulated phosphoprotein.

Sources: Michelson AD. Methods for the measurement of platelet function. *Am J Cardiol.* 2009;103(3, Suppl):20A–26A. Price MJ. Bedside evaluation of thienopyridine antiplatelet therapy. *Circulation*. 2009;119:2625–2632.

Potential reasons for clopidogrel nonresponsiveness are multifactorial. One source of nonresponsiveness is in the decreased biotransformation of clopidogrel from its prodrug form to its active metabolite. Biotransformation is a multistep process through the cytochrome P-450 system, but the most important enzyme is CYP2C19, which exhibits variable metabolic capacity. Patients with the *1/*1 CYP2C19 alleles are considered extensive metabolizers and are capable of generating sufficient levels of clopidogrel's active metabolite. Patients with one or two copies of either the *2 or *3 alleles (considered loss of function alleles) are considered either intermediate or poor metabolizers, generate lower amounts of active metabolite, and generally produce a reduced antiplatelet effect as measured with available platelet function testing.[104] Conversely, patients with one or two copies of the *17 allele (considered a gain of function allele) are considered ultrarapid metabolizers and demonstrate a heightened antiplatelet response with clopidogrel. With the unraveling of pharmacogenomic factors related to clopidogrel response, a great deal of attention has been given to the idea of identifying patients with copies of either the *2 or *3 allele and adjusting antiplatelet therapy accordingly. The FDA added language

to the clopidogrel package insert specifying that poor metabolizers have a higher cardiovascular event rate and that tests are available to identify who those patients are who carry these genes. Alternative antiplatelet agents or alternative dosing of clopidogrel should be used.[105] Expert consensus recommends against routine CYP2C19 genotyping in patients with stable CAD. Exceptions can be made in specific situations that are deemed high risk such as left main coronary artery stenting and prior stent thrombosis. Expert consensus also recommends against platelet function testing (PFT) in patients with stable CAD to determine if antiplatelet therapy should be increased, but PFT may be useful in predicting cardiovascular risk (both bleeding and ischemic events) after PCI.[106]

An alternative approach to address the issue of clopidogrel nonresponsiveness is to assess platelet function in patients receiving clopidogrel. To date, trials conducted have indicated that increasing loading or maintenance doses of clopidogrel do have the potential to convert patients deemed nonresponders to responders.[107,108] However, not all patients can be converted and no trial has demonstrated that such an approach leads to improved clinical outcomes.[109] Therefore, in chronic stable angina, increase loading and maintenance doses should not be used.

Case 12-4, Question 5: While you are filling her new clopidogrel prescription, E.R. mentions that she has been having some problems with heartburn lately and asks where she can find some OTC omeprazole. Is omeprazole appropriate to use in a patient with clopidogrel therapy?

Another source of variable clopidogrel response is through potential drug–drug interactions involving the CYP2C19 enzyme. One class of agents that has generated substantial controversy in this area are the proton-pump inhibitors (PPIs), given the likelihood of coadministration to prevent GI bleeding as a result of antiplatelet therapy. Several studies indicate there is a pharmacokinetic interaction between PPIs, in particular omeprazole, with clopidogrel resulting in reduced levels of the active metabolite. Evidence that this interaction is clinically significant is variable. Several

retrospective analyses suggest an increased risk for CVD events in patients taking PPIs with clopidogrel therapy.[110-114] However, the available evidence from randomized controlled trials does not support an increased clinical risk with this combination.[114-116] However, one study has identified that PPI use alone is associated with an elevated risk of CVD events.[117] Clinicians are faced with addressing this issue from a medical–legal aspect as the FDA has incorporated language into the clopidogrel package insert warning against the concomitant administration of omeprazole and esomeprazole with clopidogrel.[118] The recommendation applies to omeprazole and esomeprazole but not other PPIs. Drug–drug interaction studies indicated PPIs such as pantoprazole and rabeprazole have the lowest propensity for clinically significant interactions with clopidogrel. Until further information becomes available, clinicians should first validate the need for PPI therapy in clopidogrel patients. If acid-suppressive therapy is needed, the use of an H_2 antagonist (excluding cimetidine, which can inhibit CYP enzymes) or a PPI less likely to interact with clopidogrel would seem to be appropriate options to consider.[119]

VARIANT ANGINA (CORONARY ARTERY SPASM)

Clinical Presentation

CASE 12-5

Question 1: A.P., a 35-year-old female, is hospitalized for evaluation of severe chest pain, which occurs almost daily at about 5 AM. A.P. ranks the severity of pain as 7 to 8 on a scale of 1 to 10. It is associated with diaphoresis and is not relieved by change in position. A.P. has no cardiovascular risk factors, and her hobbies include triathlon competition and rock climbing, neither of which has caused chest pain. She follows a strict vegetarian diet and takes no medications. Admission ECG reveals sinus bradycardia at 56 beats/minute.

Serum electrolytes, chemistry panel, and cardiac enzymes are all within normal limits.

On day 1 of hospitalization, A.P. is awakened at 6 AM abruptly by severe chest pain. Her vital signs at this time include the following: heart rate, 55 beats/minute; supine BP, 110/64 mm Hg; and respiratory rate, 12 breaths/minute. An ECG shows sinus bradycardia with marked ST-segment elevation. The pain is relieved within 60 seconds by one NTG 0.4-mg sublingual tablet. During the day, she completes an exercise tolerance test without complication or evidence of CAD.

On the second day, A.P. undergoes cardiac catheterization, and no coronary atherosclerosis is visualized. A.P. is diagnosed as having Prinzmetal variant angina. Discharge medications include oral amlodipine 10 mg every day at 11 PM and NTG lingual spray 0.4 mg as needed for chest pain.

Is A.P.'s presentation typical for Prinzmetal variant angina?

A.P. presents with a classic picture of variant (Prinzmetal) angina, with transient total occlusion of a large epicardial coronary artery as a result of severe segmental spasm. Clinical manifestations include chest pain occurring at rest, often in the morning hours. As with A.P., patients with Prinzmetal variant angina generally are younger than patients with chronic stable angina and do not carry a high-risk profile. Other vasospastic disorders, such as migraine attacks or Raynaud phenomenon, may be present; smoking can be an important contributing factor.[120]

The hallmark of variant angina is ST-segment elevation on the ECG, which denotes rapid and complete occlusion of the coronary artery. Many patients also have asymptomatic episodes of ST-segment elevation.[120]

As documented by angiography, A.P. has vasospasm of the large RCA. This transient, reversible narrowing is probably caused by increased coronary vascular resistance. It can occur in the absence of atherosclerosis, as illustrated by A.P., and also in the presence of CAD.

Therapy

Case 12-5, Question 2: Oral amlodipine 10 mg every day was ordered for A.P. Would long-acting nitrates or β-adrenergic blockers be reasonable alternatives to amlodipine for A.P.? Is one CCB preferable to another for treatment of Prinzmetal variant angina?

Because of their antispasmodic effects and low incidence of side effects, CCBs are generally selected either alone or in combination with long-acting nitrates for nocturnal vasospastic angina. All CCBs appear equally effective in preventing Prinzmetal variant angina.[120] Intrinsically long-acting or sustained-release forms are preferred, however, and some patients may respond better to one agent than to another.

Nitrates cause vasodilation by a different mechanism than CCBs and are effective in treating Prinzmetal variant angina.[120] To avoid tolerance, the nitrate-free interval for A.P. should be scheduled during the day so that the early morning hours when vasospasm occurs are covered by NTG. For example, A.P. could apply a transdermal NTG patch at bedtime and remove it on awakening. Statin therapy is indicated for A.P.[120]

Blockade of the β_2-receptors that mediate vasodilation may allow unopposed α_1-mediated vasoconstriction with worsening symptoms. Even a cardioselective β-blocker could worsen Prinzmetal variant angina.[118] Therefore, a CCB or nitrate is preferred.

Case 12-5, Question 3: Will A.P. require treatment for the remainder of her life?

Patients often experience an acute phase of anginal episodes that occur during the first 6 months after diagnosis.[120] This occurs most often in patients who have had a short duration of symptoms or who have normal or mildly diseased coronary arteries (ie, isolated vasospasm without atherosclerosis). If A.P. is pain-free and not experiencing significant arrhythmias or silent ischemic episodes of Prinzmetal angina after 1 year, amlodipine could be tapered and discontinued. It is also possible, however, that she will require

treatment indefinitely. Modification of smoking may promote remission of Prinzmetal angina.[120]

MICROVASCULAR ANGINA

CASE 12-6

QUESTION 1: K.G., a 50-year-old female executive, has undergone an extensive cardiovascular workup for exertional angina associated with a 3-mm ST-segment depression. A recent cardiac catheterization did not reveal any atherosclerosis. The cardiologists believe K.G. has microvascular angina.

What drug therapy might be indicated for K.G.?

Microvascular angina, historically known as cardiac syndrome X, is a syndrome of angina or angina-like chest pain in the setting of a normal coronary arteriogram, and ST-segment depression during exercise. Microvascular angina is because of various coronary microvascular functional and structural abnormalities. Several subtypes exist, and subtypes respond differently to different pharmacologic options. However, currently, there is a lack of knowledge in diagnosing different microvascular anginal subtypes.[121]

By symptoms alone, K.G.'s presentation does not significantly differ from that of a patient with exercise-induced angina secondary to atherosclerosis. Of concern is the finding of a 3-mm ST-segment depression on K.G.'s ECG, which raises concern of severe CAD. The negative findings from her cardiac catheterization, however, rule against both CAD and coronary artery spasm as a cause of her symptoms, and help to confirm the diagnosis of microvascular angina.[121]

Until subtypes of microvascular angina are commonly diagnosed, traditional anginal therapy with a nitrate, CCB, or β-blocker is recommended. All appear to offer some relief, but, overall, the response to therapy in these patients is poor. Some subtypes may benefit from other agents such as ACE inhibitors, ranolazine, and

tricyclic antidepressants. The choice of agent will likely depend on specific patient characteristics. Sublingual NTG is often ineffective at treating acute attacks, although it should still be prescribed. Often a combination of anti-ischemic therapy, analgesic therapy, and lifestyle modifications is necessary.[121]

Acute Coronary Syndrome

Brianne Dunn and Robert Lee Page II

CORE PRINCIPLES		CHAPTER CASES
ACUTE CORONARY SYNDROME		
1	Acute coronary syndrome (ACS) is an umbrella term including unstable angina (UA) or acute myocardial infarction (MI), which consists of ST-segment elevation myocardial infarction (STEMI) and non–ST-segment elevation myocardial infarction (NSTEMI). Diagnosis is based on patient presentation, electrocardiographic changes, and elevated cardiac biomarkers.	**Case 13-1 (Questions 1–4)**
2	Treatment goals of ACS are to alleviate ischemic symptoms, restore blood flow to the infarct-related artery, arrest infarct expansion, minimize adverse outcomes, and prevent mortality.	**Case 13-1 (Question 5)** **Case 13-2 (Question 1)**

3	For both STEMI and non–ST-segment elevation acute coronary syndrome (NSTE-ACS), initial therapies may include oxygen, nitroglycerin (NTG), antiplatelet agents, anticoagulants, β-blocker, angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), and morphine sulfate.	**Case 13-1 (Questions 14–16)**

ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

1	Treatment goals of STEMI are to restore coronary blood flow by administering a fibrinolytic or performing percutaneous coronary intervention (PCI). Treatment strategy depends on the availability of catheterization laboratory and skilled staff, time of initial medical contact, and contraindication for a fibrinolytic agent.	**Case 13-1 (Questions 6, 11–13)**
2	Regardless of reperfusion strategy, patients should receive aspirin in addition to a $P2Y_{12}$ inhibitor.	**Case 13-1 (Questions 7–10)**
3	For patients receiving fibrinolytic therapy, unfractionated heparin (UFH), enoxaparin, or fondaparinux should also be initiated.	**Case 13-1 (Questions 7, 10)**
4	For patients receiving PCI, an anticoagulant strategy consisting of either UFH or low-molecular-weight heparins (LMWH) with or without a glycoprotein IIb/IIIa inhibitor or bivalirudin alone should be administered.	**Case 13-1 (Question 10)**

NON–ST-SEGMENT ELEVATION ACUTE CORONARY SYNDROME

1	For an invasive strategy, a $P2Y_{12}$ inhibitor (clopidogrel, prasugrel, or ticagrelor) and an anticoagulant (UFH, enoxaparin, or bivalirudin) should be administered along with aspirin. A glycoprotein IIb/IIIa inhibitor may be used adjunctively in select patients.	**Case 13-2 (Questions 2–5)**
2	For an ischemia-guided strategy, an anticoagulant (UFH, enoxaparin, or fondaparinux) along with dual antiplatelet therapy (DAPT) should be considered.	**Case 13-2 (Question 6)**

SECONDARY PREVENTION STRATEGIES

1	Potential long-term therapies include a β-blocker, statin, aspirin, $P2Y_{12}$ inhibitor, ACE inhibitor or ARB, aldosterone antagonist, and sublingual NTG. Unless contraindicated, ACE inhibitors or ARBs should be given to those with a left ventricular ejection fraction of <40%, hypertension, diabetes, and/or chronic kidney disease.	**Case 13-3 (Questions 1–3, 5, 6, 9)**
2	Lifestyle modifications include smoking cessation, weight management through diet and exercise to reduce body weight by 10% if body mass index exceeds 25 kg/m^2, diabetic treatment to achieve a near-normal hemoglobin A_{1c}, and	**Case 13-3 (Question 10)**

	hypertension management to achieve goal blood pressure ≤130/80 mm Hg.	
COMORBIDITIES		
1	Aldosterone antagonists and sodium–glucose-linked cotransporter-2 (SGLT2) inhibitors provide additional benefit for patients following an ACS event with a left ventricular ejection fraction <40%.	**Case 13-3 (Questions 2, 4)**
2	In patients with diabetes, an SGLT2 inhibitor or a glucagon-like peptide-1 receptor agonist (GLP1-RA) should be considered regardless of baseline A_{1c}.	**Case 13-3 (Question 4)**
3	Strategies to minimize bleeding risk for patients needing oral anticoagulation in addition to DAPT should be considered.	**Case 13-3 (Questions 7, 8)**

INTRODUCTION

Despite advances in medical intervention and pharmacotherapy, cardiovascular disease continues to be a leading killer in the United States. Acute coronary syndrome (ACS) is an umbrella term that includes patients who present with either unstable angina (UA) or acute myocardial infarction (AMI), which is further differentiated into ST-segment elevation myocardial infarction (STEMI) or non–ST-segment myocardial infarction (NSTEMI).[1–5] The terminology, non–ST-segment elevation acute coronary syndrome (NSTE-ACS) includes both UA and NSTEMI.[1] These two conditions are determined based on the presence (NSTEMI) or absence (UA) of biomarkers associated with necrosis. The etiology of ACS originates from the erosion or rupture of an unstable plaque within the coronary artery leading to the formation of an occlusive or a nonocclusive

thrombus. Although NSTE-ACS and STEMI lead to hospitalization, patients presenting with STEMI are considered medical emergencies and warrant immediate intervention.[5] Today, the management of ACS is based on reperfusion and revascularization using both pharmacologic and nonpharmacologic interventions such as percutaneous coronary intervention (PCI) and coronary artery bypass grafting (CABG).[1–5] A committee composed of representatives from the American College of Cardiology (ACC) and the American Heart Association (AHA) periodically review the literature and publish practice guidelines to aid health care practitioners in selecting the most effective treatments for patients with ACS.[1–5] These guidelines consist of graded recommendations based on the weight and quality of the evidence. Although there are local variations in practice, these guidelines serve as the foundation for care of patients with ACS.

Epidemiology

According to AHA statistics, an American has an AMI every 40 seconds, which accounts for ~720,000 new coronary events and 335,000 recurrent events. The average age at first MI is 65.6 years for males and 72.0 years for females.[6] In an analysis of >4 million Medicare beneficiaries, Krumholz et al estimated that 30-day mortality for acute MI declined from 1995 through 2014 (20.0%–12.4%). Mortality was higher in females, but, over time, the difference in 30-day mortality between males and females reduced. These trends may be reflective of application of evidence-based guidelines as well as aggressive treatment of hypertension and hypercholesterolemia.[7] Based on the 2016 estimates, the U.S. health care system spent a total of $89.3 billion for ischemic heart disease, of which nearly half was for inpatient care and almost one-quarter was for ambulatory care expenses.[8]

Pathophysiology

The majority of ACS cases results from occlusion of a coronary artery secondary to thrombus formation overlying a lipid-rich atheromatous plaque that has undergone fissuring or rupture (**Fig. 13-1**). Plaques that are susceptible to rupture have a thin fibrous cap, large fatty core, high content of inflammatory cells such as macrophages and lymphocytes, limited amounts of smooth muscle, and an eccentric shape. Triggers such as surges in sympathetic activity with a sudden increase in blood pressure (BP), pulse rate, myocardial contractility, and coronary blood flow can lead to erosion, fissuring, or rupture of the fragile fibrous cap. Once ruptured, the thrombogenic components of the plaque consisting of collagen and tissue factor are exposed. This promotes activation of the platelet cascade, ultimately leading to the formation of a thrombus as well as ischemia in the corresponding myocardial area. The extent of intracoronary thrombosis and distal embolization determines the type of ACS (see **Fig. 13-1**). In patients with UA, the coronary artery has enough blood flow such that the myocardial cells do not die. In patients with NSTEMI, there exists partial thrombotic occlusion with or without distal embolization or severe stenosis and some myocardial cells die. In STEMI, there exists total and persistent thrombotic occlusion leading to myocardial cell death.[9] Eighty percent of patients presenting with ACS have two or more active plaques.[9]

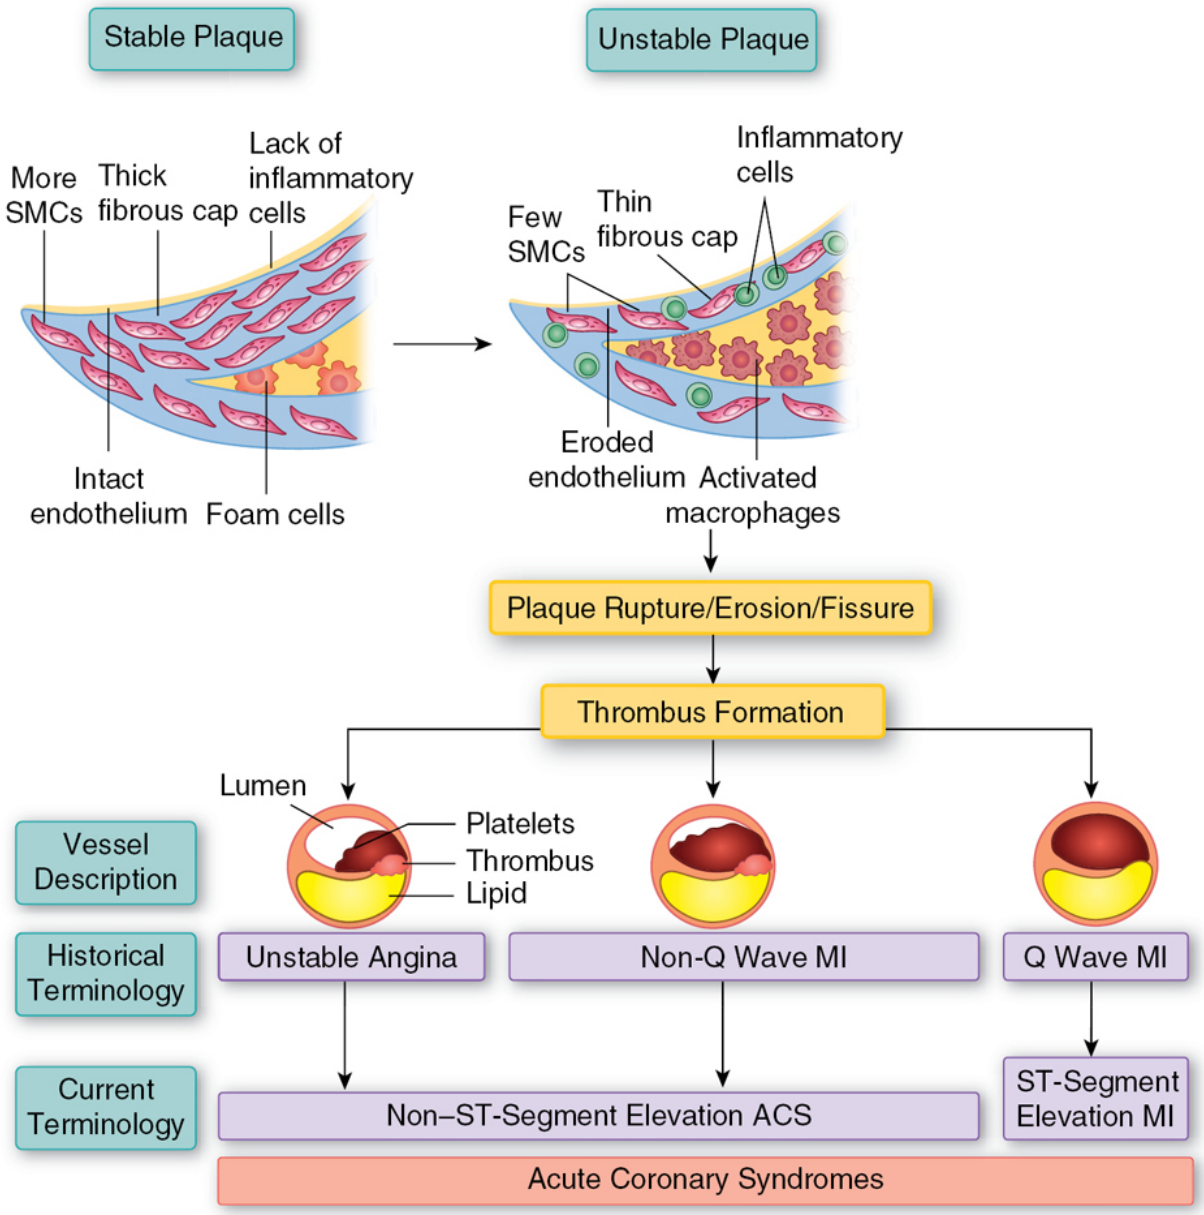

Figure 13-1 Thrombus formation and acute coronary syndrome definitions. ACS, acute coronary syndrome; MI, myocardial infarction; SMC, smooth muscle cells.

Most infarctions are located in a specific region of the heart and are described as such (eg, anterior, lateral, inferior). An anterior wall infarction carries a worse prognosis than does an inferior or lateral wall infarction because it is more commonly associated with development of left ventricular (LV) failure and cardiogenic shock.

Clinical Presentation

An important part in establishing the diagnosis of ACS is obtaining the patient's "story," which can elicit crucial hallmark symptoms such as increasing frequency of exertional angina or chest pain at rest, new-onset severe chest discomfort, or increasing angina with a duration exceeding 20 minutes. The pain is typically midline anterior chest discomfort that can radiate to the left arm, back, shoulder, or jaw and may be associated with diaphoresis, dyspnea, nausea, and vomiting, as well as unexplained syncope. Patients with STEMI will usually report unrelenting chest pain, whereas patients with NSTE-ACS will present with either angina at rest, new-onset (≤2 months) angina, or chronic angina that increases in frequency, duration, or intensity. Presentation may differ by sex, age, and presence of various comorbidities. Males commonly report chest pain, whereas females often present with nausea and diaphoresis. Elderly patients may present with hypotension or cerebrovascular symptoms rather than with chest pain. In addition, onset of ACS does not occur at random, and many episodes appear to be triggered by external factors or conditions. Myocardial infarction occurs with increased frequency in the morning, particularly within the first hour of awakening; on Mondays; during winter months or colder days; and during emotional stress and vigorous exercise.[1–5]

The physical examination is important in guiding initial therapy. Signs of severe LV or right ventricular dysfunction may be present (see Chapter 14, Heart Failure). The patient may have severe hypertension as a result of pain or, conversely, may be hypotensive. Significant tachycardia (heart rate >120 beats/minute) suggests a large area of damage. On cardiac auscultation, presence of a fourth heart sound (S_4) denotes an ischemia-induced decrease in LV compliance. New cardiac murmurs may be heard, resulting from papillary muscle dysfunction. The cerebral and peripheral vasculature should be assessed. Patients with a history of cerebrovascular disease may not be eligible for fibrinolytic therapy. Peripheral pulses should be examined to assess perfusion and to obtain a baseline before invasive procedures are instituted.

Diagnosis

In addition to the patient's history and presentation, the diagnosis of ACS is based on the electrocardiogram (ECG) and laboratory results from a cardiac injury profile. A 12-lead ECG should be obtained within 10 minutes of presenting to the emergency department (ED). The ECG is an indispensable tool in the diagnosis of ACS and has become the key point in the decision pathway (**Fig. 13-2**). Key findings on ECG consist of ST-segment elevation, ST-segment depression, or T-wave inversion.[1–5] By definition, STEMI consists of ST-segment elevation in two or more contiguous leads and either exceeding 0.2 mV (2 mm) in leads V_1, V_2, and V_3 or ≥0.1 mV (≥1 mm) in other leads. NSTE-ACS consists of ST-segment depression exceeding 0.1 mV (1 mm) in two or more contiguous leads or T-wave inversions exceeding 0.1 mV (1 mm). In addition, the 12-lead ECG is helpful in determining the location of an infarct.[10]

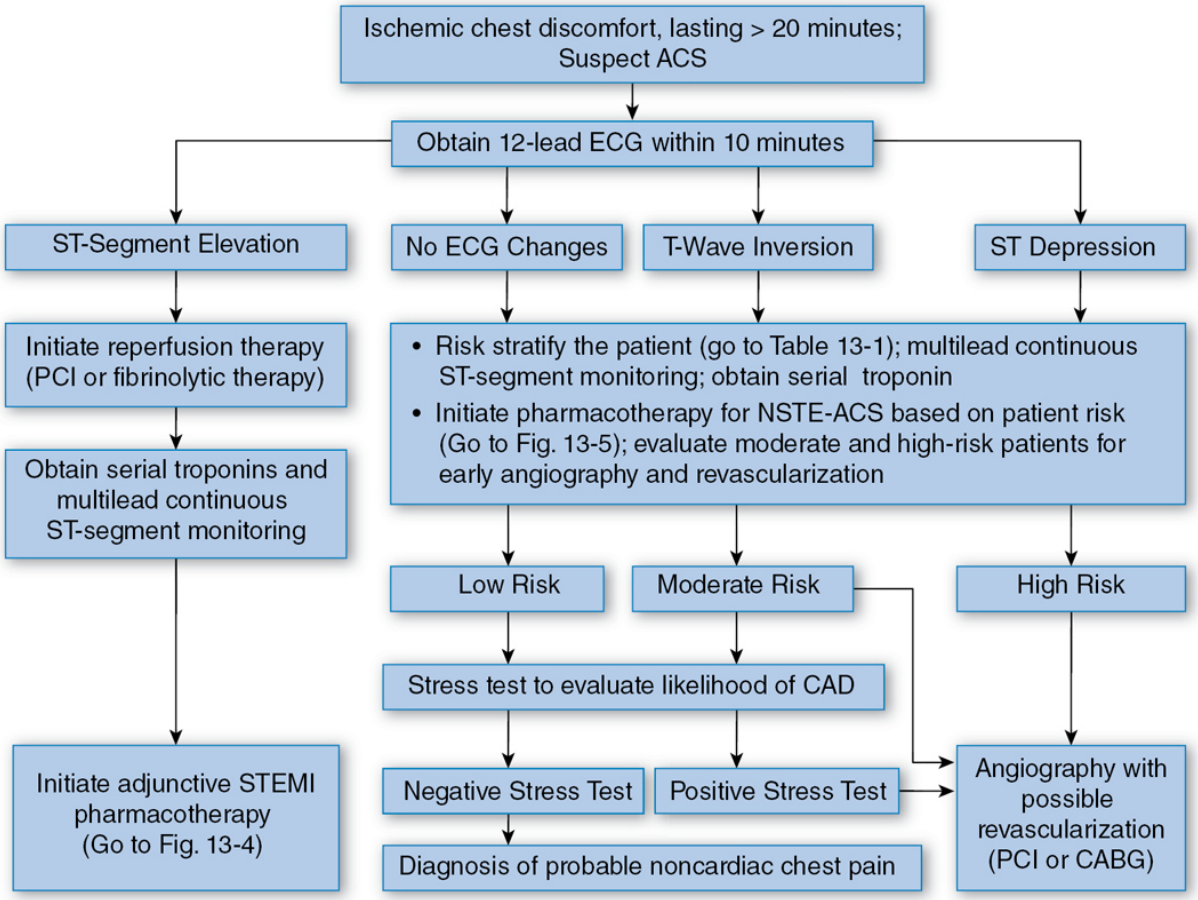

Figure 13-2 Evaluation algorithm for the patient presenting with acute coronary syndrome. ACS, acute coronary syndrome; CAD, coronary artery disease; CABG, coronary artery bypass graft; ECG, electrocardiogram; PCI, percutaneous intervention; NSTE-ACS, non–ST-segment acute coronary syndrome; STEMI, ST-segment myocardial infarction. Laboratory Changes

When a cardiac cell is injured, proteins are released into circulation. The measurement of these sensitive and specific proteins (troponins T or I and creatine kinase [CK]) is routine in establishing the diagnosis of AMI (**Fig. 13-3**). There are three isoenzymes of CK, of which the MB band is the most specific for the myocardium. Troponin is the preferred biomarker for the assessment of myocardial damage owing to its high cardiac specificity and sensitivity (90.7% and 90.2%, respectively). High-sensitivity cardiac troponin (hs-cTn) allows for more rapid detection of myocardial injury and allows for a shortened timing of serial measurements.[11] Troponins T and I are detectable in blood within 4 to 12 hours of the onset of MI, and peak values are observed at 12 to 48 hours. Troponin levels may also stay elevated for 7 to 10 days after myocardial necrosis. As seen in **Figure 13-3**, the horizontal line depicts the upper reference limit (URL) for the cardiac biomarker in the clinical chemistry laboratory.[1,2,5] The URL represents the 99th percentile of a reference control group without MI. Because cardiac troponin T and I are not normally detected in the blood of healthy people, the definition of an abnormally increased level is a value that exceeds that of 99% of a reference control group. For the diagnosis of NSTEMI or STEMI, the patient should have at least one troponin value. Cardiac biomarkers are not typically elevated in patients with UA. Presently, no current marker is detectable immediately upon onset of MI, and therefore repeated measurements of cardiac enzymes after admission are warranted. A cardiac injury profile will be measured at presentation and every 3 to 6 hours for the first 12 to 24 hours and periodically thereafter.[2–4] Unfortunately, several conditions other than AMI, such as tachyarrhythmias, heart failure (HF), myocarditis and pericarditis, hypotension or hypertension, acute pulmonary embolism, end-stage renal disease, and cardiac trauma are associated with elevated troponin. As a result, it is important to assess other diagnostic criteria such as ECG changes, chest pain, presence of atherosclerotic risk factors, and echocardiographic findings.

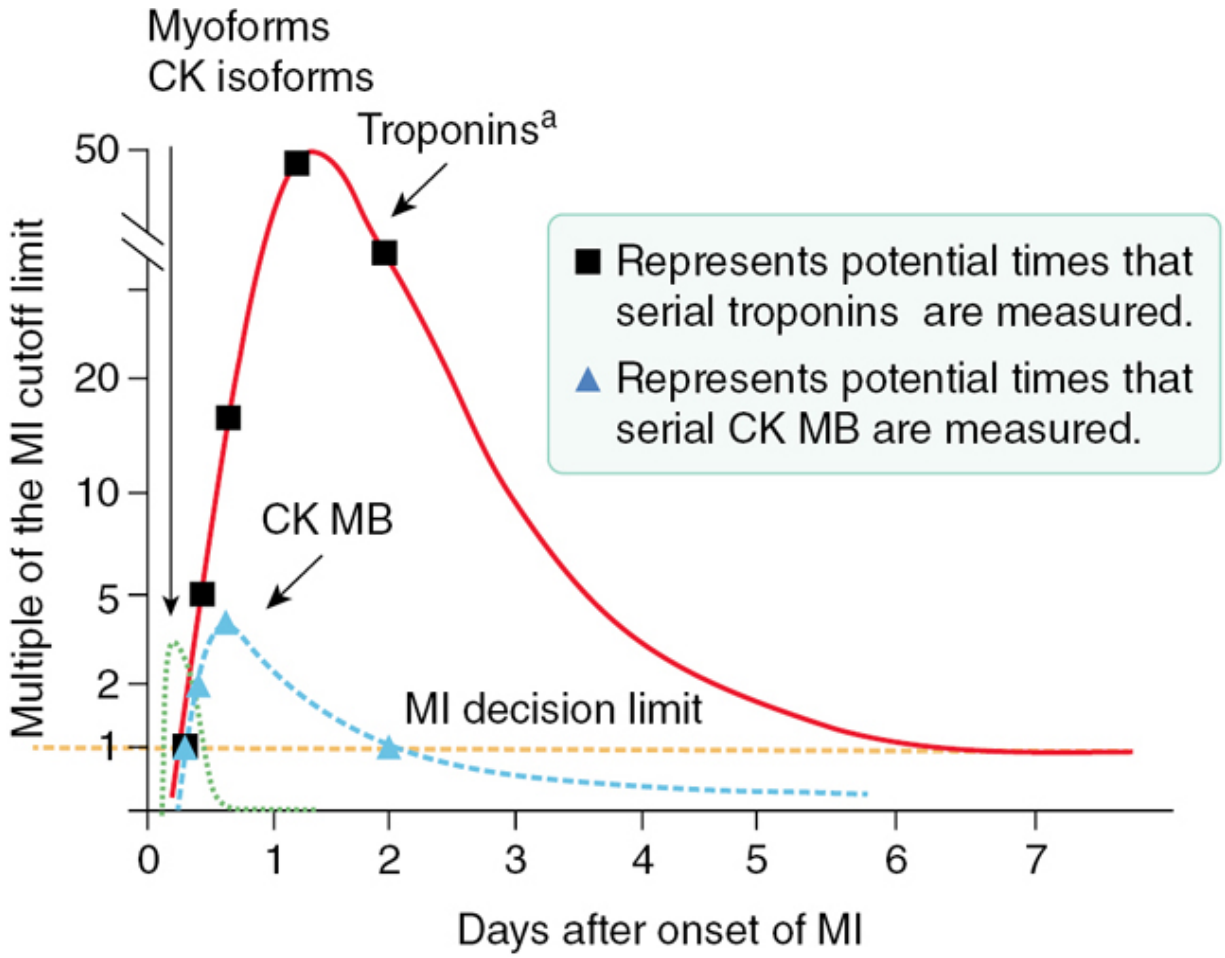

Figure 13-3 Cardiac biomarker elevation in acute coronary syndrome. CK, creatine kinase; MI, myocardial infarction.[a] Serial troponins and CK-MB are initially measured during first 12 to 24 hours of onset of chest pain and continued to be measured until the concentrations begin to decline. (Adapted from Anderson J, Adams CD, Antman EM, et al. ACC/AHA 2007 guidelines for the management of patients with unstable angina/non-ST-Elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 2002 Guidelines for the Management of Patients With Unstable Angina/Non-ST-Elevation Myocardial Infarction) developed in collaboration with the American College of Emergency Physicians, the Society for Cardiovascular Angiography and Interventions, and the Society of Thoracic Surgeons endorsed by the American Association of Cardiovascular

and Pulmonary Rehabilitation and the Society for Academic Emergency Medicine. *J Am Coll Cardiol*. 2007;50(7):e1–e157. © 2007 American College of Cardiology Foundation and the American Heart Association, Inc. With permission.)

Risk Stratification

The examination of a patient presenting with ACS begins with stratification for the risk of major adverse cardiac events (MACE), taking into account the presenting signs and symptoms, past medical history, ECG, and cardiac biomarker changes (see **Fig. 13-2**). In addition, risk scores can be used to estimate mortality and bleeding risk as well as guide decision-making for intervention. Several risk scoring systems have been validated in patients with ACS (**Table 13-1**). The two most common are the Thrombolysis in Myocardial Infarction (TIMI) risk score, which was introduced in the year 2000 and can be used with either STEMI or NSTE-ACS and the Global Registry of Acute Coronary Events (GRACE) score introduced in 2006, which estimates in-hospital and 1-year morality for patients with ACS.[12,13] The HEART score can be used as a decision aid for early discharge in low-risk patients and has been shown to better predict MACE compared to GRACE and TIMI.[14,15] Bleeding scores such as CRUSADE (*C*an *R*apid risk stratification of *U*nstable angina patients *S*uppress *AD*verse outcomes with *E*arly implementation of the ACC/AHA guidelines) can be used to estimate a patient's likelihood of major bleeding and can aid in selection of anticoagulation and antiplatelet selection.[16] Lastly, the dual antiplatelet therapy (DAPT) score was designed to identify long-term risk of extended DAPT beyond 12 months.[17] A variety of clinical tools to aid in the decision-making process can be found through the ACC and include mobile apps for ease of use. At this time, no one risk assessment strategy is preferred but, instead, is based on hospital preference and clinical experience.

Table 13-1
Risk Stratification Tools for Acute Coronary Syndrome

	TIMI Risk Score		GRACE Score		HEART Score		CRUSADE Score		DAPT Score	
Variables	Age ≥65 years	1 point	Age	0–100 points	Suspicious history	0–2 points	Heart rate	1–11 points	Age	−2 to 0 points
	≥3 risk factors for CAD	1 point	Heart rate	0–46 points	ST-segment deviation	1–2 points	Systolic BP	1–8 points	Smoking	1 point
	Prior history of CAD	1 point	Systolic BP	0–58 points	Age	0–2 points	Hematocrit	2–9 points	Diabetes	1 point
	Aspirin use in the past 7 days	1 point	Creatinine	0–28 points	1–2 risk factors for CAD	1 point	Creatinine clearance	0–35 points	MI at presentation	1 point
	≥2 anginal events in the past 24 hours	1 point	Cardiac arrest at admission	39 points	≥3 risk factors for CAD	2 points	Female gender	8 points	Prior PCI or prior MI	1 point
	ST-segment deviation ≥0.5 mm	1 point	ST-segment deviation on ECG	28 points	Elevation in cardiac markers	1–2 points	Signs of HF at presentation	7 points	Drug-eluting stent	1 point
	Elevation of cardiac markers	1 point	Abnormal cardiac enzymes	14 points			History of valvular disease	6 points	Stent diameter <3 mm	1 point
			Killip class (I–IV)	0–59 points			History of diabetes	6 points	EF < 30%	2 points
									Vein graft stent	2 points
Score Range	0–7 Low risk: 0–2 Intermediate risk: 3–4 High risk: ≥5		0–372 Low risk: <109 Intermediate risk: 109–140 High mortality risk: ≥141		0–10 Low risk: 0–3 Moderate risk: 4–6 High risk: 7–10		0–90 Very low/low risk: <31 Moderate risk: 31–40 High/very high risk: >40		−2 to 10 Favorable benefit/risk ratio: ≥2 Unfavorable benefit/risk ratio: <2

Patients with STEMI are at the highest risk for death and reinfarction, and initial treatment should proceed with immediate revascularization regardless of their risk stratification score. In the case of NSTE-ACS, a TIMI risk score of 5 to 7, 3 to 4, and 0 to 2 reflect a high, moderate, and low risk for death, MI, or need for urgent coronary artery revascularization, respectively (**Table 13-1**). A low-risk patient with negative cardiac biomarkers may undergo a stress test or be discharged from the ED with a diagnostic test scheduled within 72 hours. Moderate- and high-risk patients are often admitted to the hospital for pharmacologic treatment, further diagnostic tests, and angiography with possible intervention.

Complications

The primary complications of ACS can be divided into three major groups: pump failure, arrhythmias, and recurrent ischemia and reinfarction. Depression of cardiac function after AMI is related directly to the extent of LV damage. As a result of decreased cardiac output and decreased perfusion, a number of compensatory mechanisms become activated. The levels of circulating catecholamines increase in an attempt to increase contractility and restore normal perfusion. In addition, the renin-angiotensin-aldosterone system is enhanced, leading to an increase in systemic vascular resistance and sodium and water retention. These compensatory mechanisms can eventually worsen the imbalance between myocardial oxygen supply and consumption by increasing the myocardial oxygen demand.[18]

Signs and symptoms of HF are common in patients who have abnormal wall motion affecting 20% to 25% of the LV. If ≥40% of the LV is damaged, cardiogenic shock and death may occur. Ischemia and scar formation after an AMI may lead to a decrease in

ventricular compliance, resulting in abnormally high LV filling pressures during diastole. (See Chapter 14, Heart Failure, for further discussion on HF with reduced ejection fraction [EF] and preserved EF.)

Decreased contractility and a compensatory increase in LV end-diastolic volume and pressure lead to increased wall stress within the left ventricle. LV enlargement is an important determinant of mortality after AMI. During a period of days to months after an AMI, the infarcted area may expand as a result of dilatation and thinning of the LV wall. These changes are known as ventricular remodeling. In addition, hypertrophy of the noninfarcted myocardium occurs. Administration of oral angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), or aldosterone antagonists may limit remodeling and will attenuate the progression of LV dilatation.[19,20]

During the peri-infarction period, the heart is irritable and subject to ventricular arrhythmias. The continuous monitoring of patients in a coronary care unit has reduced the in-hospital mortality rate related to ventricular arrhythmias. However, patients who have had an AMI have an increased risk of sudden cardiac death for 1 to 2 years after hospital discharge. The most important predictor of sudden cardiac death is an abnormal left ventricular ejection fraction (LVEF). Other factors associated with an increased risk of sudden cardiac death are complex ventricular ectopy, frequent (>10/hour) premature ventricular complexes, and the identification of late potentials on a signal-averaged ECG.[18]

OVERVIEW OF DRUG AND NONDRUG THERAPY

Overlap exists regarding the pharmacotherapy for both STEMI and NSTE-ACS. According to the ACC/AHA guidelines, early therapies should consist of oxygen (if oxygen saturation is <90%), sublingual

(SL) and/or intravenous (IV) nitroglycerin (NTG), IV morphine, ACE inhibitor or ARB, aldosterone antagonist, antiplatelet agents, stool softener, β-blocker, statin, and anticoagulant. Adjunctive therapies such as analgesics and vasodilators can also be considered in selected patients. **Table 13-2** summarizes the evidence-based pharmacotherapies for both STEMI and NSTE-ACS. **Figure 13-4** provides an initial treatment algorithm for patients with STEMI, and **Figure 13-5** for patients with NSTE-ACS. Administration of these pharmacotherapies serves as a performance measure for health systems to ensure effective, timely, safe, and efficient patient-centered care.[1,5]

Table 13-2
Evidence-Based Pharmacotherapies for Acute Coronary Syndromes

Drug	Indication	Dose and Duration	Therapeutic End Points	Precautions	Comments
ACE inhibitors[a]	STEMI and NSTE-ACS within the first 24 hours of presentation for those with EF ≤40% or s/s of HF STEMI and NSTE-ACS for late hospital care for patients with hypertension, EF ≤40%, DM, or CKD STEMI and NSTE-ACS for indefinite use for all patients with EF ≤40%	Usual captopril dose 12–50 mg tid, then start longer acting ACE inhibitor Duration indefinite	Titrate to usual doses and maintain systolic BP >90 mm Hg.	Avoid IV therapy within 48 hours of infarct. Avoid initiation with systolic BP <100 mm Hg, pregnancy, acute renal failure, angioedema, bilateral renal stenosis, serum potassium ≥5.5 mEq/L.	
Angiotensin receptor blockers[a]	STEMI and NSTE-ACS with ACE inhibitor intolerance	Usual doses of ARBs (see Chapter 14, Heart Failure) Duration indefinite	Same as for ACE inhibitors	Same as for ACE inhibitors	
Aldosterone antagonists[a]	STEMI and NSTE-ACS with EF ≤40% and either DM or HF symptoms already receiving therapeutic doses of an ACE inhibitor and β-blocker	Spironolactone 12.5–50 mg daily or eplerenone 25–50 mg daily Duration indefinite	Titrate to HF symptom control without evidence of hyperkalemia	Hyperkalemia, hypotension Avoid if potassium ≥5 mEq/L or SCr ≥2.5 mg/dL for males and 2.0 mg/dL for females or CrCl ≤30 mL/minute	Dose can be increased every 4–8 weeks.
Aspirin[a]	STEMI and NSTE-ACS for all patients	162–325 mg during AMI, then 81–325 mg daily indefinitely (81 mg daily is preferred)		Active bleeding, thrombocytopenia	Unless clear contraindication exists, aspirin should be given to all patients with AMI.
Amiodarone	Treatment of VT, VF	150 mg IV over 10 minutes, repeat for recurrence, follow with 1 mg/minute IV infusion for 6 hours, then 0.5 mg/minute (maximum: 2.2 g/24 hours).	Cessation of arrhythmia	Bradycardia, hypotension	
β-Blockers[a]	STEMI and NSTE-ACS in all patients without contraindications	Variable Titrate to HR and BP. It is reasonable to administer an IV β-blocker at the time of presentation to patients with STEMI who are hypertensive and who do not have any of the following: (a) signs of HF, (b) evidence of a low-output state, (c) increased risk for cardiogenic shock[b], or (d) other relative contraindications to β-blockade (PR interval >0.24 seconds, second- or third-degree heart block, active asthma, or reactive airway disease). Duration indefinite	Titrate to resting HR ~60 beats/minute, maintain systolic BP >100 mm Hg.	Observe HR and BP closely when given IV. Contraindicated in patients with HR <50 beats/minute; PR ECG interval >0.24 seconds, second- or third-degree heart block, persistent hypotension, pulmonary edema, bronchospasm, risk of cardiogenic shock, severe reactive airway disease	Unless clear contraindication exists, β_1-selective agents such as metoprolol and atenolol should be given to all patients with AMI. In patients with systolic dysfunction, metoprolol, carvedilol, or bisoprolol can be considered.

Bivalirudin[a]	STEMI with primary PCI and NSTE-ACS with an early invasive strategy	*STEMI with primary PCI*: 0.75 mg/kg IV bolus immediately before PCI, followed by 1.75 mg/kg/hour infusion with or without UFH. *NSTE-ACS with an early invasive strategy*: 0.1 mg/kg IV bolus followed by 0.25 mg/kg/hour infusion. Continue until diagnostic angiography or PCI is performed.		Avoid in patients with active bleeding.	Reduce infusion to 1 mg/kg/hour with estimated CrCl <30 mL/minute.
Cangrelor[a]	STEMI and NSTE-ACS before PCI in patients not treated with a $P2Y_{12}$ inhibitor and are not being given a GP IIb/IIIa inhibitor	30 μg/kg IV bolus before PCI, followed immediately by a 4 μg/kg/minute IV infusion for at least 2 hours or duration of procedure, whichever is longer		Active bleeding	After discontinuation of infusion, an oral $P2Y_{12}$ inhibitor should be administered: ticagrelor 180 mg load during or upon immediate discontinuation of infusion; prasugrel 60 mg or clopidogrel 600 mg upon immediate discontinuation of infusion.
Calcium channel blockers	STEMI and NSTE-ACS for patients with ongoing ischemia who are receiving adequate doses of nitrates and β-blockers. Consider diltiazem or verapamil for patients with contraindication to β-blocker if EF is normal.	Usual doses of calcium channel blockers are used. Duration dictated by clinical scenario	Titrate to usual doses and maintain systolic BP >90 mm Hg.	Usual calcium channel blocker contraindications. Avoid nondihydropyridines in patients with pulmonary congestion or EF <40% or AV block.	In patients with normal EF, most calcium channel blockers will exert beneficial effects. Some data support use of verapamil or diltiazem for non–Q-wave AMI.
Clopidogrel[a]	STEMI and NSTE-ACS for patients allergic to aspirin	75 mg daily		Active bleeding, thrombotic thrombocytopenia purpura (rare)	
Clopidogrel + aspirin[a]	STEMI with fibrinolytic therapy, before PCI after fibrinolytic therapy, or before primary PCI. NSTE-ACS for early invasive or ischemia-guided strategies	*STEMI with fibrinolytic therapy*: 300 mg load, then continue 75 mg daily and continue for up to 1 year; aspirin 162–325 mg on first day, then 81–325 mg daily indefinitely (81 mg daily is preferred).		Active bleeding, thrombotic thrombocytopenia purpura (rare), avoid loading dose in patients ≥75 years of age, discontinue at least 5 days for CABG.	Whether administered before fibrinolytic or PCI, clopidogrel + aspirin reduced CV death, MI, or ischemia at 30 days. The 600 mg load should be considered if a GP IIb/IIIa is not used.
		lytic, then 300 mg load and for >24 hours from fibrinolytic, 600 mg load, then continue 75 mg daily if coronary stent deployed for at least 1 year; aspirin 162–325 mg on first day, then 81–325 mg daily indefinitely (81 mg is preferred) *STEMI before primary PCI*: 600 mg load, then continue 75 mg daily if coronary stent deployed for at least 1 year; aspirin 162–325 mg on first day, then 81–325 mg/day indefinitely (81 mg daily is preferred) *NSTE-ACS for early invasive or ischemia-guided strategy*: 300–600 mg load, then continue 75 mg daily for at least 1 year; aspirin 162–325 mg on first day, then 81–325 mg/day indefinitely (81 mg daily is preferred)			
Enoxaparin[a]	STEMI (as an alternative to UFH) for patients receiving fibrinolytic therapy or for those not undergoing PCI NSTE-ACS for early invasive or ischemia-guided strategies.	*STEMI with fibrinolytic therapy*: Age <75 years, administer 30 mg IV bolus followed by 1 mg/kg SQ every 12 hours (max dose of 100 mg for patients weighing ≥100 kg). Age ≥75, administer 0.75 mg/kg SQ every 12 hours (first two doses, administer max dose of 75 mg for patients weighing ≥75 kg). Continue up to 8 days or until revascularization. *NSTE-ACS for early invasive or ischemia-guided strategies*: 1 mg/kg SQ every 12 hours. A supplemental 0.3 mg/kg IV dose should be administered at the time of PCI if the last dose of SQ enoxaparin was given 8–12 hours before PCI. Continue for duration of hospitalization or until PCI.		Avoid in patients with active bleeding, history of HIT, planned CABG, SCr ≥2.5 mg/dL in males and ≥2.0 mg/dL in females, or CrCl <15 mL/minute.	For CrCl 15–29 mL/minute, reduce to 1 mg/kg every 24 hours.

Fibrinolytic therapy[a]	STEMI presenting within 12 hours of onset of symptoms, can be considered in patients presenting within 12–24 hours of onset of symptoms with continuing s/s of ischemia	*Alteplase*: 15 mg IV bolus, 50 mg for 30 minutes, then 35 mg for 60 minutes (for patients <65 kg, reduce dose) *Reteplase*: 10-unit IV bolus, second 10-unit bolus 30 minutes later *Tenecteplase*: 30–50 mg bolus over 5–10 seconds (<60 kg: 30 mg, 60–69 kg: 35 mg, 70–79 kg: 40 mg, 80–89 kg: 45 mg, 90 kg: 50 mg)	Improved TIMI grade flow	See Table 13-3.	
Drug	**Indication**	**Dose and Duration**	**Therapeutic End Points**	**Precautions**	**Comments**
Fondaparinux[a]	STEMI: alternative to UFH or LMWH in patients receiving fibrinolytic therapy or in those not undergoing PCI NSTE-ACS: alternative to UFH or LMWH for early invasive or ischemia-guided strategies Administer additional anticoagulant with factor IIa activity in patients undergoing PCI.	*STEMI*: 2.5 mg SQ daily starting on day 2 of hospitalization, continue for 8 days or until revascularization. *NSTE-ACS for early invasive or ischemia-guided strategies*: 2.5 mg SQ daily for the duration of the hospitalization or until PCI is performed.		Avoid with active bleeding or CrCl <30 mL/minute.	In STEMI, fondaparinux reduced mortality and reinfarction without increased bleeding or strokes compared with UFH, but only in patients not undergoing PCI. In NSTE-ACS, fondaparinux was at least as effective as enoxaparin but exhibited less bleeding. Can possibly be used in HIT.
GP IIb/IIIa inhibitors[a]	STEMI: in patients undergoing PCI NSTE-ACS: in patients treated with early invasive strategy and DAPT with intermediate-/high-risk features	*Dosing for STEMI PCI*: Eptifibatide:180 μg/kg IV bolus, then begin 2 μg/kg/minute infusion followed by second IV bolus of 180 μg/kg 10 minutes after first bolus, continue infusion for 12–18 hours after PCI at the discretion of the physician. Tirofiban: 25 μg/kg IV bolus followed by an infusion of 0.15 μg/kg/minute, continue up to 18 hours at the discretion of the physician Dose for NSTE-ACS with or without PCI		Avoid with active bleeding, thrombocytopenia, prior stroke. Eptifibatide: Reduce infusion by 50% in patients with CrCl <50 mL/minute; not studied in patients with SCr >4.0 mg/dL; avoid in hemodialysis. Tirofiban: Reduce infusion by 50% in patients with CrCl <30 mL/minute.	In NSTE-ACS, eptifibatide or tirofiban is FDA approved for PCI and ischemia-guided therapy. Abciximab is only for patients undergoing PCI.
		Eptifibatide: 180 μg/kg IV bolus, then begin 2 μg/kg/minute infusion, continue infusion for 12–18 hours. Repeat bolus dose after 10 minutes for PCI. Tirofiban: 25 μg/kg IV bolus within 5 minutes followed by an infusion of 0.15 μg/kg/minutes (or 0.075 μg/kg/minutes for patients with CrCl ≤60 mL/minute), for up to 18 hours.			
Heparin[a]	STEMI: for patients undergoing PCI or treated with fibrinolytic therapy NSTE-ACS: for early invasive or ischemia-guided strategies	*STEMI with fibrinolytic therapy or NSTE-ACS with early invasive or ischemia-guided strategies*: 60 units/kg IV bolus (max 4000 units) followed by 12 units/kg/hour (max 1000 units/hour) for 48 hours or until revascularization *STEMI with PCI*: 50–70 units/kg IV bolus if a GP IIb/IIIa inhibitor planned; or 70–100 units/kg IV bolus if no GP IIb/IIIa inhibitor. Continue for 48 hours or until end of PCI.	aPTT ratio 1.5–2.5× patient's control value, aPTT should be obtained 4–6 hours after initiation of infusion if not treated with fibrinolytic therapy or PCI and within 3 hours if treated with fibrinolytic therapy.	Avoid with active bleeding, thrombocytopenia, recent stroke.	Unless clear contraindication exists, UFH should be given to all patients with AMI who do not receive fibrinolytic therapy.
Morphine and other analgesics	STEMI and NSTE-ACS for patients whose symptoms not relieved by NTG or adequate anti-ischemic therapy	Morphine: 2–5 mg IV every 5–30 minutes PRN	Decreased chest pain and HR	Avoid morphine with bradycardia, right ventricular infarct, hypotension, confusion.	Has been associated with higher risk of death; discontinue nonselective NSAIDs and COX-2 selective agents.
Nitroglycerin[a]	STEMI and NSTE-ACS with persistent ischemia, hypertension, or pulmonary congestion	Variable; titrate to pain relief or systolic BP: 5–10 μg/minute titrated to 200 μg/minute. Usually maintain IV therapy for 24–48 hours after infarct.	Titrate to pain relief or systolic BP >90 mm Hg.	Avoid with systolic BP <90 mm Hg, right ventricular infarction, sildenafil or vardenafil within 24 hours or tadalafil within 48 hours.	Use acetaminophen or narcotics for headache. NTG should be tapered gradually in patients with ischemic heart disease. Topical patches or oral nitrates are useful for patients with refractory symptoms.

Prasugrel + Aspirin[a]	STEMI: before PCI after fibrinolytic therapy or before primary PCI NSTE-ACS: before PCI with coronary stenting	60-mg loading dose, then 10 mg daily (if ≥60 kg) or 5 mg (if <60 kg) if coronary stent deployed for at least 1 year; aspirin 162–325 mg on day 1, then 81–325 mg daily indefinitely (81 mg daily is preferred)		Avoid with active bleeding, prior stroke or TIA, age ≥75 years. Do not start if urgent CABG needed; discontinue 7 days before elective CABG or other surgery.	
Ticagrelor + Aspirin[a]	ACS: previous history of AMI STEMI: before primary PCI NSTE-ACS: for early invasive or ischemia-guided strategies	*ACS with previous history of MI:* Load with 180-mg oral loading dose following an ACS event, then continue treatment with 90 mg twice daily during the first year after an ACS event. After 1 year, administer 60 mg twice daily; aspirin 162–325 mg on day 1, then 81 mg daily indefinitely. *STEMI before primary PCI:* 180 mg load, then continue 90 mg bid if coronary stent deployed for at least 1 year; aspirin 162–325 mg on day 1, then 81 mg daily indefinitely. *NSTE-ACS with early invasive or ischemia-guided strategy*: 180 mg load, then continue 90 mg bid if coronary stent deployed or for both early invasive and ischemia-guided strategies for at least 1 year; aspirin 162–325 mg on day 1, then 81 mg daily indefinitely.	No firm end points	Avoid in patients with severe hepatic impairment or active bleeding. Maintenance doses of aspirin >100 mg daily can decrease ticagrelor's effectiveness. Discontinue at least 5 days before CABG.	Monitor closely for dyspnea. For at least the first 12 months following ACS, ticagrelor was found to be superior to clopidogrel. Maximum dose of simvastatin is 40 mg with ticagrelor.
Vorapaxar	ACS for secondary prevention of thrombotic cardiovascular events	1 tablet (2.08 mg) daily.		Contraindicated in history of stroke, TIA, ICH, or active bleeding	Use with aspirin and/or clopidogrel according to their indications or standard of care. No data with ticagrelor or prasugrel or with use as a single antiplatelet agent.

ACE, angiotensin-converting enzyme; AF, atrial fibrillation; AMI, acute myocardial infarction; aPTT, activated partial thromboplastin time; ARBs, angiotensin receptor blockers; bid: twice daily; BP: blood pressure; CABG, coronary artery bypass graft; CKD, chronic kidney disease; CNS, central nervous system; COX-2, cyclooxygenase-2; CrCl, creatinine clearance; CV, cardiovascular; DAPT, dual antiplatelet therapy; DM, diabetes mellitus; ECG, electrocardiogram; EF, ejection fraction; FDA, U.S. Food and Drug Administration; GP IIb/IIIa, glycoprotein IIb/IIIa inhibitor; HF, heart failure; HIT, heparin-induced thrombocytopenia; HR, heart rate; INR, international normalized ratio; ICH: intracranial hemorrhage; IV, intravenously; LMWH, low-molecular-weight heparin; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; NSTE-ACS, non–ST-segment elevation acute coronary syndrome; NTG, nitroglycerin; PCI, percutaneous coronary intervention; PRN, as needed; SCr, serum creatinine; SQ, subcutaneously; s/s, signs and symptoms; STEMI, ST-segment elevation myocardial infarction; TIA, transient ischemic attack; tid, three times a day; TIMI, Thrombolysis in Myocardial Infarction; UHF, unfractionated heparin; VF, ventricular fibrillation; VT, ventricular tachycardia.

[a]Indicates specific drug therapies that are known to reduce morbidity or mortality.

[b]Risk factors for cardiogenic shock (the greater the number of risk factors present, the higher the risk of developing cardiogenic shock) are age >70 years, systolic BP <120 mm Hg, sinus tachycardia >110 beats/minute, or heart rate <60 beats/minute.

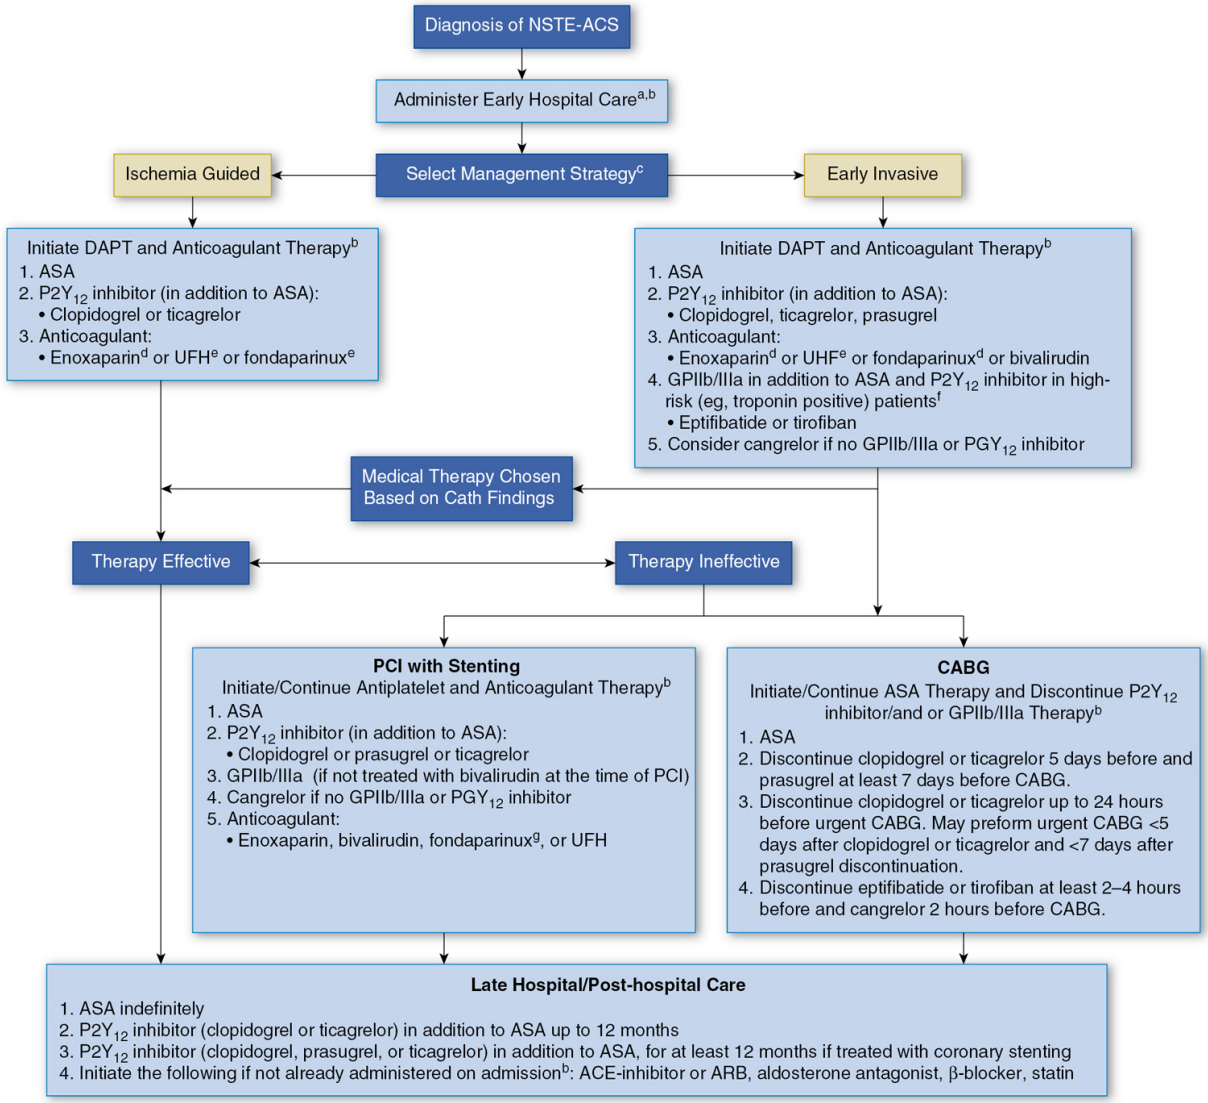

Figure 13-5 Initial treatment algorithm for NSTE-ACS.[a] Early hospital care consists of oxygen for oxygen saturation <90%, SL nitroglycerin, IV nitroglycerin, IV morphine, β-blocker, ACE inhibitor or ARB, aldosterone antagonist, stool softener, and statin.[b] Refer to Table 13-2 for indications, dosing, and contraindications.[c] An early invasive strategy would be considered if one or more of the following occurs: recurrent angina or ischemia at rest, presence of elevated cardiac biomarkers, new or presumably new ST-segment depression, signs or symptoms of HF or new worsening mitral regurgitation, hemodynamic instability, sustained ventricular tachycardia, PCI within 6 months, prior CABG, considered high risk per TIMI or GRACE risk score, LVEF <40%. An ischemia-guided

conservative strategy would be considered if the patient is classified as low-moderate risk per the TIMI or GRACE risk score or if the patient or clinician prefers this approach in the absence of high-risk features.[d] For the duration of the hospitalization, up to 8 days.[e] For at least 48 hours.[f] Factors favoring administration of a GP IIb/IIIa in addition to an ASA and a $P2Y_{12}$ inhibitor are delay to angiography, high-risk features, and early recurrent ischemia.[g] In patients who have been treated with fondaparinux (as upfront therapy) who are undergoing PCI, an additional anticoagulant with anti-IIa activity should be administered at the time of PCI owing to risk of catheter thrombosis. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; ASA, aspirin; CABG, coronary artery bypass graft; Cath, catheterization; DAPT, dual antiplatelet therapy; GP IIb/IIIa, glycoprotein IIb/IIIa; HF, heart failure; GRACE, Global Registry of Acute Coronary Events; IV, intravenous; NSTE-ACS, non–ST-segment elevation acute coronary syndrome; PCI, percutaneous coronary intervention; SL, sublingual; TIMI, Thrombolysis in Myocardial Infarction; UFH, unfractionated heparin. (Adapted from Amsterdam EA, Wenger NK, Brindis RG, et al. 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association task force on practice guidelines. *J Am Coll Cardiol*. 2014;64(24):e139–e228. © 2014 American Heart Association, Inc, and the American College of Cardiology Foundation. Fibrinolytic Drugs

Because the majority of STEMI cases result from the sudden occlusion of a coronary artery, the priority is to open the occluded artery as quickly as possible. This is accomplished by administering one of three strategies: administration of a fibrinolytic agent that enhances the body's own fibrinolytic system, mechanically reducing the obstruction with primary PCI or fibrinolysis, followed by a routine early PCI known as a pharmacoinvasive strategy or facilitated PCI.

This last strategy potentially leverages the strengths of both approaches by combining the speed and ease of fibrinolytic therapy administration with the reliability and durability of PCI, but has been studied to a more limited extent. The term *facilitated PCI* has been used when the time interval between fibrinolysis and PCI is shorter (eg, <2 hours), whereas the term *pharmacoinvasive approach* implies an intentionally longer fibrinolysis to PCI interval (eg, 2–24 hours).[21]

Large clinical trials have proved that administration of a fibrinolytic agent reduces mortality. Early mortality from STEMI was reduced by approximately one-third (from 10%–15% to 6%–10%) with fibrinolytic therapy.[5] Compared to fibrinolytic therapy, a contemporary analysis of 31 trials suggested that primary PCI reduced mortality by 27% and 21% with a pharmacoinvasive strategy.[21]

The fibrinolytic drugs currently used for patients with STEMI in the United States are fibrin-specific agents including alteplase (tissue plasminogen activator [t-PA]), reteplase (recombinant plasminogen activator [r-PA]), and tenecteplase (TNK). Alteplase, is a naturally occurring enzyme produced by recombinant DNA technology. It cleaves the same plasminogen peptide bond that urokinase cleaves. However, t-PA has a binding site for fibrin, which allows it to bind to and preferentially lyse thrombin-bound instead of circulating plasminogen. Reteplase is a genetically modified plasminogen activator that is similar to t-PA. Reteplase has a longer half-life, allowing it to be administered as two bolus injections 30 minutes apart, rather than as a bolus plus infusion. TNK is a genetically modified form of t-PA. Compared with t-PA, TNK has a longer plasma half-life, better fibrin specificity, and higher resistance to inhibition by a plasminogen activator inhibitor.[22,23] The pharmacologic properties and dosing regimens are compared in Table 13-2.

Unfortunately, an ideal fibrinolytic agent does not exist. Three problems common to all fibrinolytic drugs are the inability to open 100% of coronary artery occlusions, inconsistent ability to maintain good blood flow in the infarcted artery after it is opened, and bleeding complications. When assessing coronary artery flow after reperfusion therapy, the TIMI flow grade is used. Flow in coronary

arteries is classified as grade 0 (no flow), grade 1 (penetration without perfusion), grade 2 (partial perfusion), or grade 3 (complete perfusion).[24] When assessing an episode of bleeding, the TIMI bleeding criteria are used. TIMI major bleeding consists of overt clinical bleeding or documented intracranial or retroperitoneal hemorrhage that is associated with a drop in hemoglobin of at least 5 g/dL or hematocrit of at least 15% (absolute). TIMI minor bleeding is defined as overt clinical bleeding associated with a fall in hemoglobin of 3 to 5 g/dL or in hematocrit of 9% to 15% (absolute).[25]

To minimize the risk of bleeding complications, contraindications to the use of fibrinolytic drugs must be evaluated before administration (**Table 13-3**). There are relatively few absolute contraindications to fibrinolytic therapy, but each patient should be assessed carefully to ascertain whether the potential benefit outweighs the potential risk. Because of the serious nature of intracerebral hemorrhage, patients should be selected carefully before receiving these agents. Generally, the diagnosis of STEMI must be ensured, with a history consistent with ischemia, and presence of ST-segment elevation in two contiguous leads, or a new left bundle branch block on the ECG.[5]

Table 13-3
Risk Factors Associated With Bleeding Complications Secondary to Fibrinolytic Use[5]

Absolute Contraindications	Any prior intracranial hemorrhage
	Known structural cerebral vascular lesion (eg, arteriovenous malformation)
	Known malignant intracranial neoplasm (primary or metastatic)
	Active bleeding or bleeding diathesis (excluding menses)
	Suspected aortic dissection
	Significant closed-head or facial trauma within 3 months
	Intracranial or intraspinal surgery within 2 months
	Ischemic stroke within 3 months, except acute ischemic

	stroke within 4.5 hours
	Severe uncontrolled hypertension (unresponsive to emergency therapy)
Relative Contraindications	Uncontrolled hypertension on presentation (SBP >180 mm Hg, DBP >110 mm Hg)
	Chronic, severe, poorly controlled hypertension
	Prior ischemic stroke >3 months, dementia, or known intracranial pathology
	Puncture of a noncompressible vessel
	Major surgery (<3 weeks)
	Recent internal bleeding within 2–4 weeks
	Active peptic ulcer
	Current use of anticoagulants (the higher the INR, the greater the risk for bleeding)
	Pregnancy

DBP, diastolic blood pressure; INR, international normalized ratio; SBP, systolic blood pressure.

Fibrinolytic therapy is indicated in patients with STEMI who present to the hospital within 12 hours of symptom onset and are unable to undergo primary PCI within 120 minutes of first medical contact.[5] The benefit derived from fibrinolytic therapy is directly related to the time from the onset of chest pain to the time of administration. Although the guidelines recommend initiation within 12 hours of the onset of chest pain, data from clinical trials suggest that mortality reduction is greater when fibrinolytic therapy is initiated within 0 to 2 hours of symptom onset compared with treatment initiated >2 hours after symptoms have begun. The guidelines recommend a "door-to-needle time" of 30 minutes, meaning the diagnosis of STEMI and initiation of fibrinolytic therapy should ideally

take place within 30 minutes of the time the patient arrives at the hospital door. Once stabilized, the patient should be transferred to a facility capable of PCI in case reperfusion fails or reocclusion occurs.[5]

In patients with NSTE-ACS, fibrinolytic agents are not recommended. Thrombi in this population are primarily platelet-rich rather than fibrin-rich, and less responsive to fibrinolytic therapy.[26] In addition, data from the TIMI IIIB trials suggest that compared with placebo, alteplase was not associated with any improvement in death, MI, or failure of initial therapy but was associated with an increased incidence in fatal and nonfatal MI.[27]

Antiplatelet and Anticoagulant Drugs

When thrombolysis occurs, whether because of the administration of a fibrinolytic agent or through activation of the body's own fibrinolytic system, the fibrin clot begins to disintegrate. As the clot dissolves, there is a paradoxical increase in local thrombin generation and enhanced platelet aggregability, which may lead to rethrombosis. Antiplatelet agents (aspirin, $P2Y_{12}$ inhibitor: clopidogrel, prasugrel, ticagrelor, or cangrelor and the glycoprotein [GP] IIb/IIIa inhibitors) as well as parenteral anticoagulants (unfractionated heparin [UFH], low-molecular- weight heparins [LMWH] such as enoxaparin, fondaparinux, and direct thrombin inhibitors [DTIs] such as bivalirudin) have been used to minimize rethrombosis. UFH has several limitations, including a highly variable anticoagulant effect necessitating frequent monitoring and development of heparin-induced thrombocytopenia (<0.2%). LMWH may offer advantages compared with heparin owing to their ease of administration, improved bioavailability, and need for less monitoring. Unlike UFH, the DTIs offer better protection against thrombin reactivation after therapy discontinuation.

The GP IIb/IIIa receptor inhibitors, which are tirofiban, eptifibatide, and abciximab (Janssen Biologics B.V., The Netherlands), have traditionally been used; however, owing to drug shortages, Janssen

has stopped the manufacture of abciximab. GP IIb/IIIa receptors are abundant on the platelet surface. Platelets become activated when patients have an acute ischemic event or undergo PCI. With platelet activation, the GP IIb/IIIa receptor undergoes a conformational change that increases its affinity for binding fibrinogen. The binding of fibrinogen to receptors on platelets results in platelet aggregation, leading to thrombus formation. The GP IIb/IIIa receptor inhibitors prevent platelet aggregation by preventing fibrinogen from binding to GP IIb/IIIa receptor sites on activated platelets.[5]

Acute thrombocytopenia is a rare but recognized side effect of all three agents but is historically seen more often with abciximab.[28] The GP IIb/IIIa inhibitors are used in conjunction with other antiplatelet drugs and anticoagulants in patients with STEMI and those with NSTE-ACS undergoing PCI. Although effective when used in conjunction with fibrinolytic agents for patients with STEMI, the benefit is offset by high rates of bleeding. Therefore, routine use of GP IIb/IIIa inhibitors is not recommended with fibrinolytics.[5]

The $P2Y_{12}$ inhibitors, ticagrelor, prasugrel, and clopidogrel, have evolved to become an integral part in the management of ACS. By blocking the $P2Y_{12}$ adenosine diphosphate receptors, these agents decrease platelet activation and aggregation, increase bleeding time, and reduce blood viscosity.[1–5] Differences in antiplatelet potency, pharmacokinetics, pharmacodynamics, pharmacogenomics, and drug–drug interactions exist between the three agents (**Table 13-4**). Cangrelor is an IV agent approved to reduce the risk of thrombotic events in patients undergoing PCI. It is for patients who are not being treated with another $P2Y_{12}$ inhibitor or a GP IIb/IIIa inhibitor.[29] Compared with the oral agents, cangrelor has a very rapid onset (2 minutes) and offset of action (1 hour).[29] In the *Cangrelor versus Standard Therapy to Achieve Optimal Management of Platelet Inhibition* (CHAMPION)-PHOENIX trial, the primary composite end point of death, MI, ischemia-driven revascularization, or stent thrombosis at 48 hours occurred in significantly fewer patients treated with IV cangrelor compared to oral clopidogrel (4.7% vs 5.9%, $P = .005$). Although the benefit persisted at 30 days, it came at

the expense of an increase in bleeding, with rates of about 1 in 170 with cangrelor versus 1 in 275 with clopidogrel.[30] Controversy surrounds the use of pharmacogenomic and platelet function testing when determining whether a patient may be a "responder" or "nonresponder" to clopidogrel therapy.[31] At this time, the ACC/AHA guidelines do not recommend routine testing for genetic variants. See Chapter 12, Chronic Stable Angina, for more details about these controversies.

Table 13-4
Comparison of $P2Y_{12}$ Inhibitors

Parameter	Clopidogrel	Prasugrel	Ticagrelor	Cangrelor
Class	Thienopyridine (second generation)	Thienopyridine (third generation)	Cyclopentyltriazolopyrimidine	Stabilized ATP analog
Administration	Oral	Oral	Oral	Intravenous
Dose	300–600 mg LD 75 daily	60 mg LD 10 mg daily	180 mg LD 90 mg bid (60 mg bid for years 1–3)	30 μg/kg bolus 4 μg/kg/minute infusion
Age	—	If age >75 years, not recommended unless history of DM or MI	—	—
Weight	—	If <60 kg, consider 5 mg daily	—	—
FDA Indications	ACS (NSTEMI, STEMI) Recent MI, stroke, PAD	*July 2009* NSTE-ACS + PCI STEMI + PCI	*July 2011* ACS (NSTE-ACS, STEMI)	*June 2015* PCI
Trials in ACS	CURE, PCI-CURE, CREDO, ACUITY, CLARITY, COMMIT	TRITON-TIMI 38 TRILOGY-ACS	PLATO PEGASUS TIMI-54	CHAMPION-PCI CHAMPION-PLATFORM CHAMPION-PHOENIX
Receptor Binding	Irreversible	Irreversible	Reversible	Reversible
Activation	Prodrug, limited by metabolism	Prodrug, *not* limited by metabolism	Active drug	Active drug
Interpatient variability	High	Low	Low	Low
Bioavailability	~50%	80%–100%	36%	NA
Onset of action	2–6 hours	30 minutes	0.5–2 hours	2 minutes
Peak platelet inhibition	300 mg LD (6 hours) 600 mg LD (2 hours)	60 mg LD (1–1.5 hours)	180 mg LD (<1 hour)	30 μg/kg bolus (2 minutes)
Duration	3–10 days	5–10 days	1–3 days	1–2 hours
Half-life	6 hours	7 hours	7 hours	3–6 minutes
Metabolism	Hepatic via CYP450 (1A2, 3A4)	Minimal	Hepatic via CYP450 (main: 3A4, 2B6) (lesser: 2C9, 2C19)	Dephosphorylation by nucleotidases
Elimination	Urine 50% Feces 46%	Urine 68% Feces 27%	Urine 26% Feces 58%	Urine 58% Feces 35%
CYP2C19 Allele	Significant	Nonsignificant	Nonsignificant	Nonsignificant

Non-CABG major bleeding	Increased	>Clopidogrel	>Clopidogrel (overall) Similar in PCI	Similar (depending on definition)
CABG major bleeding	Increased	>Clopidogrel	= Clopidogrel Mortality benefit	Similar to placebo
Safe in stroke	Yes	Contraindicated	Similar stroke rate as clopidogrel Increased intracranial hemorrhage	Similar stroke rate as clopidogrel
Dyspnea/ bradyarrhythmia	No	No	Yes	Yes
Platelet inhibition	~50%	~70%	>80%	100%
Drug–Drug Interactions	PPIs inhibit CYP 2C19 (concomitant use with omeprazole is discouraged per package labeling); enhanced bleeding with NSAIDs, oral anticoagulants, etc.	Minimal; enhanced bleeding with NSAIDs, oral anticoagulants, etc	Strong CYP 3A4 inhibitors and inducers; max of simvastatin 40 mg; may increase digoxin concentrations; limit aspirin <100 mg/day; enhanced bleeding with NSAIDs, oral anticoagulants, etc	Enhanced bleeding with NSAIDs, oral anticoagulants, etc
Drug–Disease Interactions	—	—	Careful with asthma, bradycardia, and, possibly, gout	Careful with asthma
Boxed warning	Genetic polymorphisms	Age-related bleeding Prior TIA/stroke	Prior intracranial hemorrhage Aspirin dosing >100 mg	NA
CABG hold time	5 days	7 days	5 days	1 hour

ACS, acute coronary syndrome; ATP, adenosine triphosphate; bid, twice daily; CABG, coronary artery bypass graft; CYP, cytochrome P450; LD, loading dose; MI, myocardial infarction; NA, not applicable; NSAIDs: nonsteroidal anti-inflammatory drugs; NSTE-ACS, non–ST-elevation acute coronary syndrome; NSTEMI, non-ST segment elevation myocardial infarction; PAD, peripheral arterial disease; PCI, percutaneous coronary intervention; PPIs, proton-pump inhibitors; STEMI, ST-segment elevation myocardial infarction; TIA, transient ischemic attack.

Vorapaxar is an oral antiplatelet that selectively inhibits the cellular actions of thrombin through antagonism of platelet protease–activated receptor-1 and is indicated for secondary prevention of cardiovascular events in patients who have a history of MI or peripheral vascular disease. In the *T*hrombin-*R*eceptor *A*ntagonist in secondary *P*revention of atherothrombotic ischemic events–*T*hrombolysis *i*n *M*yocardial *I*nfarction (TRA2P–TIMI50) trial, patients with a history of MI, ischemic stroke, or peripheral arterial disease who received vorapaxar 2.5 daily had 13% reduction in the

combined end point of death from cardiovascular causes, MI, or stroke ($P < .001$) and a 12% reduction in the combined end point of cardiovascular death, MI, stroke, or recurrent ischemia leading to revascularization ($P = .001$) compared to placebo.[32] However, patients receiving vorapaxar had an increase in moderate and severe bleeding including intracranial hemorrhage. Owing to these findings and its high cost, the use of this agent has been limited in clinical practice.

a-Blockers

β-Blockers should be administered to patients with ACS unless a contraindication is present. In patients with ACS receiving either fibrinolytic therapy or PCI, β-blockers significantly decreased the rates of cardiovascular mortality, recurrent nonfatal MI, and all-cause mortality.[1–5] The 2014 ACC/AHA guidelines recommend that oral β-blocker therapy be initiated within 24 hours of the onset of symptoms for all patients without signs of HF, evidence of low-output state, increased risk of cardiogenic shock, or other contraindications. Both β-selective and nonselective agents have been evaluated; however, β-blockers with intrinsic sympathomimetic activity should be avoided because they lack efficacy data. For patients with tachycardia or hypertension without signs of HF, IV β-blockers followed by oral administration can be considered. Unless there are contraindications to their use, β-blocking agents should be prescribed for all patients after an AMI for at least 3 years and indefinitely for those with HF.[5,33]

Lipid-Lowering Agents

β-Hydroxy-β-methylglutaryl-CoA (HMG-CoA) reductase inhibitors (statins) reduce long-term morbidity and mortality in patients with cardiovascular disease. Beyond their lipid-lowering properties, statins are believed to exhibit pleiotropic effects, which include plaque stabilization, anti-inflammation, antithrombogenicity, enhancement of arterial compliance, and modulation of endothelial

function.[34] Data regarding early intensive statin therapy in patients with STEMI or NSTE-ACS exist with atorvastatin, simvastatin, pravastatin, rosuvastatin, and fluvastatin.[1,5,35] Recent ACC/AHA cholesterol guidelines recommend that patients receive a high-intensity statin such as atorvastatin 40 to 80 mg or rosuvastatin ≥20 mg daily to achieve a ≥50% reduction in low-density lipoprotein (LDL) levels. However, if LDL levels remain ≥70 mg/dL (≥1.8 mmol/L) on maximally tolerated statin therapy, adding ezetimibe followed by a proprotein convertase subtilisin/kexin type 9 (PCSK-9) inhibitor may be reasonable taking into account the cost benefit. The ODYSSEY OUTCOMES trial (ODYSSEY Outcomes: Evaluation of Cardiovascular Outcomes After an Acute Coronary Syndrome During Treatment With Alirocumab) and the FOURIER trial (*F*urther cardiovascular *OU*tcomes *R*esearch with PCSK9 *I*nhibition in subjects with *E*levated *R*isk), found that the addition of alirocumab or evolocumab, respectively, in patients on maximal statin ± ezetimibe with ACS, observed a 15% relative risk reduction in composite atherosclerotic cardiovascular disease (ASCVD) events. Moderate-intensity statins could be considered in patients age older than 75 years or those unable to tolerate high-intensity statins[36] (see Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).

Vasodilators

Other strategies for minimizing myocardial damage include the use of vasodilators in the peri-infarction period. Progressive LV dilatation ("remodeling") occurs in some patients after an AMI and has become an important marker for prognosis. Vasodilators reduce oxygen demand and myocardial wall stress by reducing afterload or preload and can attenuate the remodeling process. Some vasodilators may increase the blood supply to the myocardium by enhancing coronary vasodilatation.[1,5]

ACE inhibitors have been assessed in a large number of clinical trials, and all trials using oral agents have demonstrated a reduction in mortality.[1,5] IV ACE inhibitors should be avoided because they

cause excessive hypotension and do not improve survival. The benefit of ACE inhibitors is greatest in patients with anterior infarction, signs of HF, or a history of previous infarction. Ideally, oral ACE inhibitors should be started within 24 hours of diagnosis, after BP and renal function have stabilized. Initial doses should be low and then titrated as quickly as possible.[1,5] The ACC/AHA guidelines recommend an ARB in patients with ACS who cannot tolerate ACE inhibitors. The combination of an ACE inhibitor and ARB should be avoided because of an increase in adverse events such as hyperkalemia.

Aldosterone antagonists such as spironolactone and eplerenone have been associated with improved LV structural remodeling and performance by increasing LVEF and decreasing LV end-diastolic and end-systolic volumes. In the *E*plerenone *P*ost Acute Myocardial Infarction *H*eart Failure *E*fficacy and *SU*rvival *S*tudy (EPHESUS), patients with AMI and LV dysfunction (LVEF <40%) with or without HF were randomized 3 to 14 days after AMI to receive eplerenone. Eplerenone was found to decrease long-term mortality as an adjunct to ACE inhibitors and β-blockers.[37] Aldosterone blockade is recommended in patients following an MI with an LVEF <40% with either diabetes or symptoms of HF, assuming they have no contraindications.[1]

Nitrates dilate venous capacitance vessels and peripheral arterioles. Their predominant effect is a decrease in preload, with a lesser effect on afterload. Consequently, nitrates lead to a decrease in both myocardial wall stress and oxygen demand. IV NTG should be used in patients who have refractory ischemic discomfort (chest pain), acute HF, and/or hypertension. Hemodynamic targets are a systolic BP 100 to 130 mm Hg with a heart rate <100 beats/minute.

Other vasodilators that have been investigated in the treatment of ACS are the calcium channel blockers. There are several proposed mechanisms whereby a calcium channel blocker might be beneficial. As a group, they dilate coronary and peripheral vessels. They also alleviate some of the coronary vasospasms present at the time of coronary thrombosis. In addition, they are effective anti-ischemic

agents through their action in improving coronary blood supply and reducing myocardial oxygen demand.[1,5]

The ACC/AHA guidelines recommend calcium channel blockers for patients with persistent or recurrent symptoms after treatment with full-dose nitrates and β-blockers, for patients with contraindications to β-blockade, and for patients with Prinzmetal or variant angina. For such patients, calcium channel blockers that slow the heart rate (eg, diltiazem or verapamil) are recommended. These nondihydropyridines should not be administered to patients with LV dysfunction or pulmonary edema. The Danish Verapamil Infarction Trial (DAVIT) evaluated the efficacy of verapamil for patients with ACS.[38] There was a trend toward lower MI and mortality rates when verapamil was given to patients with suspected ACS. Similar reductions in MI and refractory angina rates have been demonstrated with diltiazem.[39] The dihydropyridine calcium antagonists amlodipine and felodipine have not been evaluated specifically for administration to patients with ACS, but trials involving normotensive patients with coronary artery disease (CAD) or patients with hypertension and cardiovascular risk factors have demonstrated that these agents provide significant benefits in reducing cardiovascular events.[40,41]

Analgesics

It is important to abolish the patient's pain as quickly as possible because pain and anxiety associated with an AMI will contribute to increased myocardial oxygen demand. If the pain is not relieved by medications (eg, nitrates, β-blockers), then additional analgesia may be necessary. Morphine sulfate (2- to 4-mg IV with increments of 2- to 8-mg IV repeated at 5- to 15-minute intervals) is the analgesic of choice for management of pain associated with STEMI. In addition to diminishing pain and anxiety, morphine also has beneficial hemodynamic effects. By reducing pain and anxiety, the release of circulating catecholamines is diminished, possibly reducing the associated arrhythmias. Morphine also causes peripheral venous

and arterial vasodilation, which reduces preload and afterload and, consequently, myocardial oxygen demand. However, retrospective studies have suggested the potential for increased mortality in patients with NSTE-ACS receiving morphine; thus, morphine carries a Class IIb recommendation in the 2014 ACC/AHA NSTE-ACS guidelines.[42] Clinicians should be aware of potential unwanted side effects of morphine such as hypotension, nausea, and respiratory depression.

The nonselective and cyclooxygenase (COX)-2–selective nonsteroidal anti-inflammatory drugs (NSAIDs) have been associated with an increased risk of mortality, reinfarction, hypertension, HF, and myocardial rupture. These agents should be discontinued at the time a patient presents with ACS.[1,5]

Stool Softeners

It is common to administer agents such as docusate to prevent constipation in patients with AMI because straining causes undesirable stress on the cardiovascular system.[1,5]

Oxygen

Many patients are modestly hypoxemic during the initial hours of an AMI. Supplemental oxygen should be administered to patients with ACS with an arterial saturation <90%, respiratory distress, or other high-risk features for hypoxemia. Patients with severe hypoxemia or pulmonary edema may require intubation and mechanical ventilation.[1,5]

Antiarrhythmic Agents

Ventricular arrhythmias, including ventricular fibrillation, are common complications associated with myocardial ischemia and AMI as well as a major cause of death. More than half of the episodes of ventricular fibrillation that occur with an AMI are within 1 hour of the

onset of symptoms. If an antiarrhythmic agent is necessary, amiodarone is preferred over lidocaine (see Chapter 15, Cardiac Arrhythmias). The routine use of prophylactic lidocaine or other antiarrhythmic agents to prevent ventricular tachycardia and ventricular fibrillation is not recommended. Although lidocaine may reduce the number of episodes of ventricular fibrillation, it may contribute to an increased number of episodes of asystole.[5]

Suppression of ventricular ectopy after an AMI with the chronic use of oral antiarrhythmic agents is not recommended. Results of the Cardiac Arrhythmia Suppression Trial (CAST) showed an increase in mortality in asymptomatic patients with ventricular ectopy after an AMI who were treated with flecainide, encainide, or moricizine (see Chapter 15, Cardiac Arrhythmias).[43,44]

Nondrug Therapy

For STEMI, primary PCI is the preferred method for reperfusion as long as it can be performed in a timely manner. Specific guidelines have been published by the ACC/AHA addressing PCI and stent use in AMI.[45]

For patients presenting to a PCI-capable hospital, PCI should be performed within 90 minutes of initial medical contact (also referred to as “door-to-balloon time”). If a patient is at a non-PCI facility, immediate transfer for primary PCI is preferred only if PCI can be performed within 120 minutes of first medical contact.[5] This threshold is based on a multivariable analysis of patients undergoing PCI in which an increased door-to-balloon time exceeding 120 minutes was associated with a higher mortality rate.[46] Fibrinolytic therapy should be given to patients when the 120-minute time goal cannot be met, unless a contraindication is present.[5]

The disadvantages of PCI include the longer amount of time needed to mobilize the personnel needed to prepare the catheterization laboratory and its initial higher cost. A potential advantage of PCI is the greater ability to achieve TIMI grade 3 flow in the affected vessel compared to fibrinolytic therapy (90% vs 50%–

60%, respectively).[5] PCI is associated with fewer MACE, irrespective of patient presentation time. In addition, rates of major bleeding and intracranial hemorrhage are lower with PCI compared to fibrinolytic therapy. Unfortunately, many hospitals do not have the facilities or skilled personnel to complete this procedure in the necessary time frame.[5]

For NSTE-ACS, coronary angiography aids in defining the extent and location of the coronary lesion and in directing the definitive care strategy (eg, PCI with stent placement, CABG, or medical management). However, because angiography is an invasive procedure, there is a small risk of serious complications. Therefore, coronary angiography should be used only in patients for whom the procedure's benefits outweigh its risks. With this principle in mind, two pathways of treatment for patients with NSTE-ACS have emerged: the early invasive strategy and the ischemia-guided strategy (**Fig. 13-5**). In the early invasive strategy, all patients without contraindications undergo coronary angiography with the intent to perform revascularization within 24 hours of hospital admission. The ischemia-guided strategy consists of aggressive medical therapy for all patients and coronary angiography only for those with certain risk factors or those who fail medical therapy.

CLINICAL PRESENTATION OF ACUTE CORONARY SYNDROME

CASE 13-1

QUESTION 1: P.H., a 68-year-old, 176.37-pound (80-kg) male, is being admitted to the ED after experiencing an episode of sustained chest pain while mowing his yard. After waiting 6 hours, he called 911 and was transported to the ED to a facility without the ability to conduct PCI. Physical examination reveals an anxious and diaphoretic male. Heart rate and rhythm are regular, and no S_3 or S_4 sounds are present. Vital signs include BP 180/110 mm Hg, heart rate 105 beats/minute, and respiratory rate 32 breaths/minute. P.H.'s chest pain radiates to his left arm and jaw, and he describes the pain as "crushing" and "like an

elephant sitting on my chest." He rates it as a "10/10" in intensity. Thus far, his pain has not responded to five SL NTG tablets at home and three more in the ambulance. His ECG reveals a 3-mm ST-segment elevation and Q waves in leads I and V_2 to V_4. Based on his history and physical examination, P.H. is diagnosed with an anterior infarction. Laboratory values include the following:

Sodium (Na^+), 141 mEq/L
Potassium (K^+), 3.9 mEq/L
Chloride (Cl^-), 100 mEq/L
Carbon dioxide (CO_2), 20 mEq/L
Blood urea nitrogen (BUN), 19 mg/dL
Serum creatinine (SCr), 1.2 mg/dL
Glucose, 149 mg/dL
Magnesium (Mg), 2 mEq/L
Troponin I-Ultra, 60 ng/mL (normal, <0.02 ng/mL)
Total cholesterol, 259 mg/dL
Triglycerides, 300 mg/dL

P.H. has a prior history of CAD. A previous cardiac catheterization 2 years ago revealed lesions in his middle left anterior descending coronary artery (75% stenosis) and proximal left circumflex artery (30% stenosis). His echocardiogram at the time showed an EF of 58%. These lesions were deemed suitable for medical management. He also has a history of recurrent bouts of bronchitis associated with bronchospasm for 10 years, diabetes mellitus treated with insulin for 18 years with a hemoglobin A_{1c} of 6.8% obtained 6 months before admission, and hypertension with BP usually 140/85 mm Hg. His father died of an MI at age 53. His mother and siblings are all alive and well. P.H. has smoked one pack of cigarettes a day for 30 years, and he drinks approximately one six-pack of beer a week. He has no history of IV drug use. On admission, P.H.'s medications include insulin glargine 40 units daily; albuterol inhaler as needed (PRN) for shortness of breath; hydrochlorothiazide 25 mg daily; NTG patch 0.2 mg/hour; and NTG SL 0.4 mg PRN for chest pain.

What signs and symptoms that are consistent with the diagnosis of AMI does P.H. have?

P.H. described his pain as a pressure sensation, which is common with ischemic heart disease. The chest discomfort associated with ACS often is described as pressure or as a tight band around the chest rather than pain. Although P.H. was involved in physical exertion when his chest discomfort began, this is not always the case. It can begin at rest and, frequently, in the early morning hours. At least 20% of patients with AMI have no pain or discomfort; these

episodes are described as “silent” MIs.[5] Presentations range from no symptoms to shortness of breath, hypotension, HF, syncope, or ventricular arrhythmias. Silent or atypical infarctions occur more commonly in people with diabetes and in the elderly. P.H. is diaphoretic, a common finding, but other common symptoms such as nausea and anxiety are not present. He also describes his pain as “10/10” in intensity, or perhaps “the worst pain I’ve ever experienced,” which is typical of a STEMI. The diagnosis primarily lies in the symptoms (eg, the patient’s “story”), the ECG, and the laboratory findings.

The history of diabetes, hypertension, smoking, and a positive family history in P.H. are all risk factors for coronary disease. His admission BP is high, which could indicate poor underlying control or anxiety and stress related to his ACS. The blood sugar of 149 mg/dL is high, again indicating either poor control or a stress response. Measurement of hemoglobin A_{1c} is indicated during his hospitalization to better assess his diabetes control.

Laboratory Abnormalities

Case 13-1, Question 2: What laboratory abnormalities can you expect to see in P.H.?

P.H. has an elevated troponin, which is consistent with myocardial necrosis and consistent with laboratory abnormalities seen with both STEMI and NSTEMI. With UA, cardiac biomarkers are not elevated. Several other nonspecific laboratory findings should be monitored in P.H. Hyperglycemia may develop because P.H. has diabetes, but this can also occur in patients without diabetes. ACS is also accompanied by an acute systemic inflammatory response manifested by fever, leukocytosis, and elevation of the erythrocyte sedimentation rate and C-reactive protein, as well as a drop in LDL, high-density lipoprotein (HDL), and total cholesterol. Specifically, these lipoprotein changes may begin to decrease within 24 to 48

hours of an ACS event, reaching a nadir within 5 to 7 days and then gradually recovering during the next 30 days.[47] Therefore, it is prudent to check serum lipid profiles within the first 24 hours of the AMI to get an accurate determination of the patient's lipid values.

ST-Segment Elevation Myocardial Infarction Versus Non–ST-Segment Elevation Myocardial Infarction

Case 13-1, Question 3: P.H. was noted to have ST-segment elevation on the ECG. What are the implications of an ST-segment elevation versus non–ST-segment elevation MI?

Perhaps the most important diagnostic test in someone suspected of having an AMI is the ECG. The ECG is an important tool because it is noninvasive, can be performed rapidly, is readily available in most settings, and helps determine where the AMI is located (ie, anterior, inferior, lateral). P.H. has classic ECG changes (ST-segment elevation), and presence in the anterior ECG leads (V_2–V_4) points to the coronary artery likely to be blocked. P.H.'s previous left anterior descending lesion may have had a plaque rupture leading to thrombosis of the vessel.

The presence of ST-segment elevation in two contiguous leads indicates severe ischemia and occlusion of the coronary artery. Every effort should be made to open the infarct-related artery as soon as possible, which could consist of PCI or fibrinolytic therapy. If the ECG showed ST-segment depression (eg, NSTE-ACS), instead of elevation, P.H. would not be eligible for fibrinolytic therapy because the risks of fibrinolytic therapy outweigh the benefits in NSTE-ACS.

Anterior Versus Inferior Infarction

Case 13-1, Question 4: What are the prognostic implications of an anterior versus an inferior MI?

Damage to the anterior section of the heart is more likely to be associated with increased morbidity (eg, LV dysfunction) and mortality. The patients at highest risk for death are those with an anterior ACS, LV dysfunction, and complex ventricular ectopy. P.H. is at an increased risk because he has sustained an anterior infarction.

Risk Stratification

Therapeutic Objectives

Case 13-1, Question 5: What are the immediate and long-term therapeutic objectives in treating P.H.?

With both STEMI and NSTE-ACS, the immediate therapeutic objectives, particularly as they apply to P.H., are to restore blood flow to the infarct-related artery, arrest infarct expansion, alleviate his symptoms, and prevent death. These objectives are achieved primarily by restoring coronary blood flow (administering a fibrinolytic or performing PCI for STEMI or performing PCI with NSTE-ACS) and lowering myocardial oxygen demand with nitrates and β-blockers. Any life-threatening ventricular arrhythmias that develop must be treated. The long-term therapeutic objectives are to prevent or minimize recurrent ischemic symptoms, reinfarction, HF, and sudden cardiac death. Because P.H. is experiencing a STEMI, the specific therapeutic regimens are discussed in the questions that follow.

TREATMENT FOR ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

Fibrinolytic Therapy

Case 13-1, Question 6: Is P.H. a candidate for fibrinolytic therapy? Is any one agent preferred?

STEMI is a medical emergency, and rapid administration of drug therapy is crucial to save myocardial tissue. The results of several major trials have shown unequivocally that if used appropriately, fibrinolytic agents can reduce the mortality associated with an AMI. Because mortality benefit is greatest when fibrinolytic therapy is administered within 2 hours of symptom onset, prehospital fibrinolytic therapy, in which trained paramedics administer the fibrinolytic in the field, is an attractive option to reduce total ischemic time, although it is not typically done in the United States.[48] If primary PCI cannot be performed within 120 minutes, fibrinolytic therapy should be given if no contraindications are present. For patients who present >12 hours after symptom onset, fibrinolytic therapy should be administered only if there is ongoing ischemic, hemodynamic instability or a large area of myocardium involvement. In the case of P.H., he is admitted to a hospital that is not PCI capable and cannot be transferred to a PCI-capable hospital within 120 minutes of first medical contact.

Controversy still exists about which fibrinolytic should be used, the best dosing regimen, the most appropriate adjunctive therapy, and whether the risk outweighs the benefit in some subpopulations of patients (eg, those with an inferior AMI). P.H. has a history of hypertension, and, at presentation, his BP is 180/110 mm Hg. A BP this high is a relative contraindication to fibrinolytic therapy because of an increased risk of cerebral hemorrhage; however, P.H. has an anterior MI and is likely to benefit from fibrinolytic therapy. In this case, he should receive IV NTG immediately because the onset of BP control with this agent usually occurs within minutes. Once his systolic BP is <180 mm Hg and the diastolic is <110 mm Hg, a fibrinolytic can be administered. The NTG will also reduce the workload on his heart and may provide pain relief. During and

following administration of the fibrinolytic, P.H.'s BP should be closely monitored to ensure it remains <180/105 mm Hg to reduce the risk of intracranial hemorrhage.

Because P.H. has severe pain and ECG changes consistent with an anterior AMI, he is at high risk for substantial morbidity or mortality. The argument for or against a specific fibrinolytic is probably less important than the decision to use an agent and to administer the medication as soon as possible after the onset of symptoms. P.H. is fortunate because he has presented within 1 hour of the onset of chest pain.

Reteplase was compared with t-PA in the *G*lobal *U*tilization of *S*treptokinase and *t*-PA for *O*ccluded Arteries (GUSTO)-III trial.[49] Reteplase has a slower clearance from the body, allowing the drug to be given as a bolus without the need for a constant infusion. In the GUSTO-III trial, reteplase was administered in two bolus doses of 10 million units, given 30 minutes apart. The mortality rate and incidence of stroke were the same in the two groups of patients. TNK was compared with t-PA in the second Assessment of Safety and Efficacy of a New Fibrinolytic (ASSENT-2) trial.[50] TNK was administered as a bolus of 30 to 50 mg for 5 to 10 seconds, based on body weight. No difference existed between TNK and t-PA in 30-day mortality and stroke, and TNK had fewer bleeding complications. Current guidelines do not explicitly endorse one fibrinolytic versus another, and all are acceptable first-line agents. Selection is usually based on clinician preference and hospital formulary.

ADJUNCT THERAPY

CASE 13-1, QUESTION 7: Orders are written for an infusion of t-PA along with UFH 4000 units IV bolus, followed by 960 units/hour by continuous infusion. Aspirin 325 mg is ordered stat. Are both UFH and aspirin agents necessary?

The second International Study of Infarct Survival (ISIS)-2 trial showed that the combination of aspirin and streptokinase reduced mortality in patients with an AMI by 42% compared to placebo.[51] In

doses of ≥162 mg, aspirin generates a prompt clinical antithrombotic effect as a result of its inhibition of thromboxane A_2 production. Thus, immediate administration of 162 to 325 mg of aspirin in all patients diagnosed with ACS is indicated. In the acute setting, aspirin should be chewed because it is absorbed more quickly. All patients should receive low-dose aspirin indefinitely after a diagnosis of ACS. If patients have a contraindication to aspirin, clopidogrel can be substituted.[5]

The use of UFH as adjunct therapy to prevent reocclusion has been evaluated in many studies.[5] Because P.H. will receive t-PA, an IV UFH bolus followed by a continuous infusion should be started before the end of the t-PA infusion. The ACC/AHA guidelines recommend an initial UFH bolus of 60 units/kg (maximum of 4000 units), followed by an initial infusion of 12 units/kg/hour (maximum of 1000 units/hour) for 48 hours after fibrinolysis, with a targeted activated partial thromboplastin time (aPTT) of 1.5 to 2 times the upper limit of normal, equivalent to anti-Xa concentrations of 0.4 to 0.7 units/mL assessed by anti-factor Xa determinations. UFH should always be considered in patients at high risk for systemic or venous embolism.

CASE 13-1, QUESTION 8: Would P.H. benefit from the addition of clopidogrel to his current drug regimen?

Two studies have evaluated the potential role of in-hospital clopidogrel as an integral part of fibrinolytic therapy in patients with STEMI.[52,53] The *CL*opidogrel as *A*djunctive *R*eperfus*I*on Therap*Y*–Thrombolysis in Myocardial Infarction 28 (CLARITY-TIMI 28) evaluated patients with STEMI who received standard fibrinolytic therapy, aspirin, and UFH, and were scheduled for angiography within 2 days.[53] Patients received either clopidogrel (300 mg loading dose, followed by 75 mg daily) or placebo within 10 minutes of fibrinolytic administration. Clopidogrel was continued up to and including the day of angiography and then stopped. The primary end point was the composite of an occluded infarct-related artery on

predischarge angiography or death or an MI up to the start of coronary angiography. Compared with placebo, patients receiving clopidogrel demonstrated a 36% reduction in the primary end point ($P < .001$). By 30 days, the clopidogrel treatment group had a 20% reduction in cardiovascular death, recurrent MI, or recurrent ischemia ($P = .03$). No difference in the rate of major bleeding was seen between groups. In a substudy of patients proceeding to nonemergent PCI after fibrinolytic therapy, patients receiving pretreatment with clopidogrel demonstrated a 66% reduction in 30-day mortality compared with those receiving placebo ($P = .034$).[54]

The *C*l*O*pidogrel and *M*etoprolol in *M*yocardial *I*nfarction *T*rial (COMMIT) evaluated the effect of clopidogrel 75 mg daily (with no loading dose) or placebo in 45,852 patients presenting with STEMI.[52] In the trial population, 93% had ST-segment elevation or bundle branch block, 7% had ST-segment depression, and 54% were treated with fibrinolytic therapy. The initial clopidogrel dose was given within 24 hours of symptom onset and continued until hospital discharge or up to 4 weeks in the hospital. Compared with placebo, clopidogrel was associated with a 9% reduction in death, reinfarction, or stroke ($P = .002$) and a 7% reduction in all-cause mortality ($P = .03$). No significant excess in bleeding was noted with clopidogrel, either overall or in patients who received concomitant fibrinolytic therapy or were older than age 70 years. On the basis of these two studies, P.H. should receive clopidogrel as an inpatient.

Case 13-1, Question 9: What dose of clopidogrel should be considered?

According to the 2013 ACC/AHA guidelines, clopidogrel should be added to aspirin in patients who undergo reperfusion with fibrinolytic therapy.[5] A loading dose of clopidogrel 300 mg can be administered with fibrinolytic therapy followed by 75 mg/day for maintenance. The maintenance dose should be continued for 14 days and up to 1 year. The 1-year duration is extrapolated from experience with NSTE-ACS.[1] There are no studies evaluating a 600-mg loading dose in patients with STEMI treated with fibrinolytics. In addition, uncertainty

exists about the safety of giving a loading dose of clopidogrel in adults ages 75 years and older, particularly when they receive a fibrinolytic. Therefore, in this population, a loading dose should be avoided. A single loading dose of 300 mg of clopidogrel should be given to patients age younger than 75 years who receive a fibrinolytic agent and are subsequently proceeding to PCI within 24 hours.[5] If the patient received a fibrinolytic (with 300 mg of clopidogrel) and then proceeds to PCI after 24 hours has lapsed, then an additional 300 mg of clopidogrel should be administered. For P.H., a loading dose of 300 mg of clopidogrel should be administered at the time of fibrinolytic administration followed by 75 mg/day for 14 days to 1 year. Because P.H. has already received 325 mg of aspirin in the ED, he should continue 81 mg of daily aspirin indefinitely.

CASE 13-1, QUESTION 10: What roles do the other anticoagulant and antiplatelet agents have in P.H.'s management?

Data available with the newer $P2Y_{12}$ inhibitors when used in the setting of fibrinolytic therapy are lacking. It would be prudent to avoid giving prasugrel and other potent $P2Y_{12}$ inhibitors no sooner than 24 hours after administration of a fibrinolytic.[5] Coronary anatomy should be known to ensure that the patient is not a candidate for CABG.

The replacement of UFH with an LMWH, factor Xa inhibitor, or the addition of a GP IIb/IIIa inhibitor to fibrinolytic therapy has been evaluated in patients with STEMI.

In the *E*nox*a*parin and *T*hrombolysis *R*eperfusion for *A*cute myocardial infar*C*tion *T*reatment–Thrombolysis in Myocardial Infarction Study-25 (ExTRACT-TIMI 25), 20,506 patients with STEMI scheduled for fibrinolytic therapy were randomized to receive either enoxaparin or continuous infusion of UFH for 48 hours.[55] Enoxaparin was dosed according to age and renal function. UFH was dosed according to weight and adjusted to achieve an aPTT 1.5 to 2 times control. The composite end point of death or nonfatal MI through 30 days occurred in 12% in the UFH group and 9.9% in the enoxaparin group, representing a 17% risk reduction ($P < .001$). No difference

was noted in mortality between the two groups. Major bleeding was higher in the enoxaparin group.

The Organization for the Assessment of Strategies for Ischemic Syndromes (OASIS) 6 was a randomized double-blind trial of 12,092 patients with STEMI assessing the effect of early initiation of fondaparinux with primary PCI and medical therapy.[56] The study compared the effects of fondaparinux with two different control arms. Patients with confirmed STEMI were assigned to one of the two following strata. Stratum 1: no indication for UFH (patients receiving streptokinase or those not receiving a thrombolytic agent were assigned to this stratum). Stratum 2: indication for UFH (patients receiving alteplase, reteplase, or TNK and those undergoing primary PCI were assigned to this stratum). Death or reinfarction at 30 days was significantly reduced in the fondaparinux group. However, fondaparinux did not benefit patients who were managed with primary PCI. Although the rates of death, MI, and severe bleeds did not differ in these patients, there was a higher rate of catheter thrombosis with fondaparinux.[56]

The TIMI-14 trial demonstrated enhanced reperfusion (TIMI 3 flow) using reduced-dose t-PA combined with abciximab compared with full-dose t-PA alone.[57] The GUSTO-V trial compared standard-dose reteplase to half-dose reteplase plus full-dose abciximab in patients with STEMI.[58] The combination group had less reinfarction and recurrent ischemia, but more episodes of moderate and severe bleeding, especially in the elderly. Similar rates of enhanced reperfusion have also been observed with the combination of a double-bolus dose of eptifibatide (180/90 μg/kg, 10 minutes apart) with a 48-hour infusion (2 μg/kg/minute) plus a half-dose of t-PA (50 mg).[59] The ASSENT-3 trial assessed three regimens: (1) full-dose TNK plus enoxaparin, (2) full-dose TNK plus UFH, or (3) half-dose TNK plus UFH with a 12-hour infusion of abciximab. The addition of either abciximab or enoxaparin to TNK reduced the composite end point of 30-day mortality, in-hospital reinfarction, or ischemia compared with UFH. More major bleeding complications were seen with abciximab compared with UFH.[60] In a meta-analysis of 11 trials involving 27,115 patients with STEMI who received adjunctive

abciximab in addition to either PCI or fibrinolytic therapy, use of abciximab was associated with a significant reduction in 30-day (*P* = .047) and 1- to 6-month mortality (*P* = .01) in patients undergoing PCI, but not in those receiving fibrinolytic therapy.[61] Despite an improvement in patency rates, the combination of GP IIb/IIIa inhibitors with either full- or half-dose fibrinolytic should be avoided, if at all possible, especially in the elderly.[5]

Based on data from ExTRACT-TIMI 25 and OASIS-6, the ACC/AHA guidelines allow for substitution of UFH with either enoxaparin or fondaparinux.[5] However, fondaparinux appeared to be superior to control therapy in the OASIS-6 trial, whereas relative benefit compared with placebo and UFH separately cannot be reliably determined.[62] If enoxaparin or fondaparinux is selected, anticoagulation should be continued for the duration of the hospitalization, up to 8 days or until revascularization. For P.H., enoxaparin would be the more appropriate choice; however, he will have a higher risk of bleeding and need to be monitored closely. Because P.H. is not undergoing PCI, the bleeding risks outweigh any benefit from the addition of a GP IIb/IIIa at this time.[5]

DETERMINATION OF REPERFUSION

Case 13-1, Question 11: How can you monitor for successful reperfusion in P.H. after he has received fibrinolytic therapy?

It is important to determine whether thrombolysis has been successful because the prognosis of the patient is related to the presence or absence of an open infarct-related artery. If fibrinolytic therapy fails to open the infarct-related artery, then the patient may benefit from PCI or a CABG. Although coronary angiography has been the standard for determining the success of reperfusion, this procedure is expensive and may be misleading because some studies have suggested that microvascular perfusion may be impaired even when TIMI grade 3 flow has been achieved. A simple and readily available technique is evaluation of ECG ST-segment

resolution. A resolution of >50% of the ST-segment elevation at 60 to 90 minutes after the initiation of fibrinolytic therapy is a good indicator of improved myocardial perfusion.[5] Relief of symptoms, maintenance or restoration of hemodynamic or electrical stability or both, and a reduction of >70% in the initial ST-segment elevation are all suggestive of adequate reperfusion. P.H. should undergo a 12-lead ECG to evaluate reperfusion.[5]

CASE 13-1, QUESTION 12: P.H. continues to have chest pain. Should the thrombolytic be readministered?

READMINISTRATION OF THROMBOLYTIC AGENTS

Reocclusion of the infarct-related artery after an initial successful thrombolysis is a major setback. If reocclusion occurs, mechanical intervention (eg, PCI) is often attempted. Several studies have evaluated whether to readminister the fibrinolytic or refer the patient for PCI. In a meta-analysis of eight trials of patients with STEMI who failed fibrinolytic therapy, those receiving rescue PCI showed no significant reduction in all-cause mortality but had a 27% risk reduction in HF (P = .05) and 42% reduction in reinfarction (P = .04) when compared with standard medical therapy. Repeat fibrinolytic therapy was not associated with significant improvements in all-cause mortality or reinfarction. Both treatment strategies demonstrated a significant increase in minor bleeding, but PCI was associated with an increase in stroke.[63] The Rapid Early Action for Coronary Treatment (REACT) study found that patients who received rescue PCI compared to repeat fibrinolytic or conservative care had a significantly lower composite of death, reinfarction, stroke, or severe HF at 6 months (event-free survival rate: 84.6% vs 70.1% vs 68.7%, respectively, P = .004).[64] The ACC/AHA guidelines recommend that patients who have failed fibrinolytic therapy undergo catheterization with appropriate antithrombotic therapy if possible.[5] Patients best suited for catheterization consist of those with high-risk features such as cardiogenic shock, significant hypotension, severe HF, or ECG evidence of an extensive area of myocardial jeopardy.

In the case of P.H., a repeat infusion with t-PA would probably be safe, but it may not be effective. If a PCI-capable institution exists, P.H. should be transferred for an invasive strategy at this time.

USE IN THE ELDERLY

CASE 13-1, QUESTION 13: If P.H. had been 85 years old, would he have still received fibrinolytic therapy?

Some of the early trials with fibrinolytic therapy excluded the elderly. Although the elderly may have a higher prevalence of relative contraindications such as severe hypertension or history of stroke at presentation, they also have a higher incidence of mortality after an AMI. The 30-day mortality rate after an AMI is 19.6% for patients between ages 75 and 85 years and 30.3% for those who are age 85 years.[65] In the ISIS-2 trial, the greatest reduction in mortality occurred in the elderly subgroup. There are no controlled trials in which fibrinolytic therapy has increased mortality in the elderly. However, in a high-risk cohort of elderly female patients (older than 75 years, <147.71 pounds [<67 kg]), the ASSENT investigators demonstrated that TNK was associated with lower rates of major bleeding and intracerebral hemorrhage compared to t-PA. Another potential strategy to reduce intracranial hemorrhage risk is a reduced dose of fibrinolytic. The *ST*rategic *R*eperfusion *E*arly *A*fter *M*yocardial infarction (STREAM) trial, evaluated prehospital fibrinolytic therapy and reduced the dose of TNK by 50% in patients age 75 years or older.[65] The intracranial hemorrhage rate was reduced to 0.5% and coronary patency rates were similar when compared to patients younger than 75 years of age who received full-dose TNK. It is also important to ensure that appropriate dosage adjustments are made for concomitant medications according to age, weight, and renal function as applicable (see **Table 13-2**).

a-Blockers

Case 13-1, Question 14: The physician wishes to write a prescription for a β-blocker. What are the benefits of administering a β-blocker to P.H.? Should it be given as IV therapy or started as oral therapy a few days after the infarction?

β-Blockers offer significant benefits to the patient with MI. Several large trials gave IV β-blockers (up to 24 hours after symptom onset) followed by oral therapy; other studies used oral therapy alone beginning days after the infarction. Early IV administration appears to be most beneficial, with a reduction in mortality of about 25% in the first 2 days when the results of these trials are pooled. However, late oral therapy alone, initiated up to 21 days after an MI in the β-Blocker in Heart Attack Trial, was also associated with a substantial reduction in mortality (around 10%).[5]

Early IV administration of propranolol, metoprolol, timolol, and atenolol has been studied. Typically, metoprolol is used in the acute setting because of its β_1 selectivity, ease of dosing and administration, and weight of evidence. Oral carvedilol, a nonselective β- and α-blocker, has been used in the peri-infarction period, specifically in patients with LV dysfunction. In the *CA*rvedilol *P*ost-infa*R*ction surv*I*val *CO*nt*R*ol in left ventricular dysfunctio*N* (CAPRICORN) trial, carvedilol 6.25 mg twice daily titrated to 25 mg twice daily reduced all-cause and cardiovascular mortality as well as recurrent nonfatal MI.[66]

It is important to tailor β-blocker therapy for each patient, as evidenced in the COMMIT trial.[67] In this study, patients were randomized to placebo or metoprolol (up to 15 mg IV of metoprolol, then oral 200 mg metoprolol succinate daily) within 24 hours of AMI. Although metoprolol reduced reinfarction and ventricular fibrillation rates compared with placebo, it was associated with a significant increase in cardiogenic shock. Patients with hemodynamic instability at randomization were at greatest risk for early cardiogenic shock associated with metoprolol. Given these concerns, oral β-blockers are generally preferred. If the patient is hypertensive or having ongoing ischemia, then IV metoprolol tartrate (5 mg IV every 5 minutes as tolerated up to three doses) can be considered (see

Table 13-2). For all other patients without contraindications, oral metoprolol tartrate 25 to 50 mg every 6 to 12 hours should be initiated. Doses should be titrated on the basis of BP and heart rate. If a patient has transient cardiac decompensation or is at risk for cardiogenic shock during the acute infarction period, early IV β-blockers should be withheld. The patient's condition may be observed for a few days; if it stabilizes, oral therapy is initiated and titrated slowly. The ACC/AHA guidelines highlight the importance of an individualized approach but do provide guidance on suggested dosing recommendations for both acute and long-term use.

In our case, P.H.'s situation is complicated by his history of intermittent pulmonary problems. In deciding whether to attempt use of β-blockers in patients with pulmonary disease, one must determine the nature of the pulmonary problem (ie, reactive airway disease). It also would be helpful to determine P.H.'s need for routine use of β-agonists to help quantify the severity of his disease. By history, P.H. does not use β-agonist bronchodilators routinely. No history is given regarding his pulmonary function tests or the degree of reversibility of his airway disease with bronchodilators. β_1-selective antagonists are the drugs of choice in these patients, but at higher doses (eg, metoprolol doses >100 mg/day), the relative β_1-selectivity may be lost. A patient would need to experience significant worsening of the pulmonary disease to justify avoiding β-blockers. A better history of P.H.'s pulmonary problems should be obtained. If they are minor and as he has experienced an uncomplicated MI, P.H. may be a candidate for early therapy with metoprolol to reduce chest pain as well as decrease the risk of reinfarction and arrhythmias.

Nitroglycerin

Case 13-1, Question 15: Despite SL NTG, P.H. continues to have chest discomfort. Would he benefit from IV NTG?

Because P.H. is exhibiting refractory ischemic discomfort despite receiving SL and topical nitrates, symptomatic management with IV NTG is indicated. NTG lowers the LV filling pressure and systemic vascular resistance, thereby reducing myocardial oxygen consumption and myocardial ischemia. At lower doses (<50 µg/minute), IV NTG preferentially dilates the venous capacitance vessels, which leads to a decrease in LV filling pressure. For patients who have signs of pulmonary congestion, IV NTG is of particular value.

CASE 13-1, QUESTION 16: How should IV NTG be administered to P.H.? How should it be monitored?

A continuous infusion of NTG is delivered in a controlled manner, starting with 5 to 10 µg/minute, which is then increased by an additional 5 to 10 µg/minute every 5 to 10 minutes if needed. Many cardiologists routinely give patients an infusion of NTG for the first 24 to 48 hours after an AMI. Increasing doses may be required during this period to maintain the desired hemodynamic effect owing to tolerance that occurs from prolonged nitrate exposure. However, if >200 µg/minute is needed to achieve the desired response, another vasodilator may be needed. NTG is typically administered in combination with fibrinolytic agents in patients who require relief from myocardial ischemia.

Patients with an inferior or a right ventricular infarct often develop hypotension (mean BP <80 mm Hg) when given NTG. P.H.'s BP should be monitored closely during this infusion. After starting NTG, we would expect to see his BP decline; the pulse rate may or may not increase. The NTG dose should be titrated to relieve pain while avoiding symptomatic hypotension. In patients with evidence of HF, NTG can reduce LV filling pressure (preload) as well as improve orthopnea and pulmonary congestion. However, excessive doses of IV NTG can reduce LV filling pressure to excess, and potentially decrease cardiac output. The systolic BP should be maintained to at least 90 mm Hg. Once P.H.'s chest pain is controlled, he may be

either transitioned to an oral agent or his transdermal delivery system increased. With either choice, a nitrate-free interval should be maintained (see Chapter 12, Chronic Stable Angina).

Treatment for Unstable Angina or Non–ST-Segment Elevation Myocardial Infarction

Invasive Versus Ischemia-Guided Strategy

CASE 13-2

QUESTION 1: J.W. is a 65-year-old male who presents to the ED with chest tightness and shortness of breath. He gives a history of similar symptoms the previous day that lasted 20 minutes. He was given aspirin 325 mg, intranasal oxygen, PO (by mouth) metoprolol tartrate, and started on an IV NTG infusion, which was increased to 80 µg/minute; at that time, his BP was 130/60 mm Hg, and his heart rate was 88. His ECG revealed ST-segment depression in the anterior leads. His shortness of breath was relieved, but he still reported chest tightness. His past medical history includes hypertension for which he takes hydrochlorothiazide 25 mg daily. His mother died of a heart attack at age 62. He has smoked a pack of cigarettes per day for the past 30 years. Laboratory values include the following:

Na^+, 135 mEq/L
K^+, 4.0 mEq/L
Cl^-, 100 mEq/L
CO_2, 20 mEq/L
BUN, 15 mg/dL
SCr, 1.1 mg/dL
Glucose, 100 mg/dL
Mg, 2 mEq/L
Troponin I-Ultra, 0.01 ng/mL (normal, <0.02 ng/mL)
Hgb, 14 g/dL
Hct, 44%
Platelets, 288 × $10^3/mm^3$

Based on his symptoms and ECG, the diagnosis is presumed to be UI.

Should J.W. receive an invasive or ischemia-guided strategy for management of his NSTE-ACS?

Although J.W. has negative biomarkers after 24 hours from his first episode of chest pain suggesting UA, the presence of new ST-segment depression may prompt the clinician to choose an early invasive approach within 24 hours (see **Fig. 13-5**). If, however, the patient is not at high or intermediate risk, then the invasive approach may be delayed and performed within 25 to 72 hours. A TIMI (or GRACE) score would also be helpful to risk stratify the patient. J.W. has a TIMI score of 4 indicating a 19.9% risk at 14 days of all-cause mortality, new or recurrent MI, or severe recurrent ischemia requiring urgent revascularization. When risk stratifying, TIMI scores of 0 to 2, 3 to 4, and 5 to 7 represent low, moderate, and high risk for death or repeat MI at 14 days. So, based on his TIMI score, he is moderate risk. As an alternative, calculating a GRACE score would indicate 137 points representing an 11% risk of in-hospital death or MI and a 19% risk at 6 months. An ischemia-guided strategy might be selected based on patient or clinician preference in the absence of high-risk features such as elevated biomarkers. In this approach, pharmacotherapy would be initiated followed by a noninvasive stress evaluation. If J.W. were to have elevated cardiac biomarkers during his presentation, his diagnosis would be NSTEMI, and an early invasive (within 24 hours) approach may be preferred. If during his hospitalization, J.W. were to experience any recurrent ischemia, arrhythmias, or signs and symptoms of HF, he would proceed directly to angiography and undergo possible PCI.

Anticoagulant Therapy

Case 13-2, Question 2: What anticoagulant regimen should J.W. receive?

The ACC/AHA guidelines recommend beginning anticoagulant therapy for all patients (without contraindications) with NSTE-ACS as soon as possible. The guidelines recommend one of four agents: UFH, enoxaparin, fondaparinux, or bivalirudin (approved only for patients managed according to an invasive strategy). **Table 13-2**

summarizes the dosing and contraindications for each of these agents.

In NSTE-ACS, UFH has been associated with lower rates of death or MI than with aspirin alone.[1] Despite its limitations, UFH is preferred if the patient is to undergo CABG because of its rapid clearance. For an invasive strategy, the guidelines give a higher level of evidence for enoxaparin but do warn about an increase in bleeding.[1] When choosing an anticoagulant, renal function, bleeding risk, and concomitant therapy should be considered.

Data supporting LMWHs in this setting come from several studies. In the Efficacy and Safety of Subcutaneous Enoxaparin in Non–Q-Wave Coronary Events (ESSENCE) study, enoxaparin (1 mg/kg subcutaneous [SQ] twice daily) was compared with UFH (5000 units IV bolus followed by continued infusion titrated to an aPTT of 55–86 seconds).[68] The composite outcome of death, MI, or recurrent angina at 14 days was reduced by 20% in the enoxaparin group. This benefit was maintained for 1 year.

In the *S*uperior *Y*ield of the *N*ew strategy of *E*noxaparin, *R*evascularization and *G*l*Y*coprotein IIb/IIIa inhibitors (SYNERGY) trial, 9978 high-risk patients with NSTE-ACS were randomized to enoxaparin (1 mg/kg SQ twice daily) or weight-based UFH (60 units/kg bolus followed by 12 units/kg/hour adjusted to an aPTT 1.5 to 2 times control) before undergoing an early invasive strategy.[69] Enoxaparin was found to be as efficacious as UFH in reducing 30-day all-cause mortality or nonfatal MI but was associated with a significant risk of major bleeding ($P = .008$). Bleeding was especially problematic in those patients who crossed over from one treatment to the other during the trial.

In the TIMI-11B trial, enoxaparin (30 mg IV bolus followed by 1 mg/kg SQ twice daily for 8 days) compared with UFH (70 units/kg bolus followed by 15 units/kg/hour for 3–8 days) reduced the composite end point of death, MI, or need for urgent revascularization.[70] The benefit of enoxaparin is greatest for high-risk subgroups such as those with ST-segment changes, elevated troponins, and a high TIMI risk score.[1]

Finally, enoxaparin has been compared with fondaparinux. In the OASIS-5 trial, patients with NSTE-ACS were randomized to fondaparinux (2.5 mg SQ daily) or enoxaparin (1 mg/kg SQ twice daily) for a mean of 6 days and evaluated at 9 days for the primary end point of death, MI, or refractory ischemia.[71] There was no difference between groups for the primary end point; however, compared with enoxaparin, fondaparinux had a significantly lower incidence of major bleeding at 9 days ($P < .001$) and a greater reduction in mortality at 30 days ($P = .05$). Based on these data, the guidelines give preference to fondaparinux compared with other anticoagulants for patients who are at an increased risk for bleeding and being treated with an ischemia-guided (conservative medical management) strategy. If fondaparinux is used for a patient undergoing PCI, an additional anticoagulant with factor IIa activity such as UFH is needed.[1]

Bivalirudin is given a Class I recommendation in the guidelines. In the *A*cute *C*atheterization and *U*rgent *I*ntervention *T*riage strateg*Y* (ACUITY) trial, patients with NSTE-ACS managed with an early invasive strategy were randomly assigned to receive either UFH (or enoxaparin) plus a GP IIb/IIIa inhibitor, bivalirudin plus a GP IIb/IIIa inhibitor, or bivalirudin alone.[72] No differences in the primary end point (composite of death, MI, unplanned revascularization for ischemia, and major bleeding at 30 days) were observed between the group receiving UFH plus a GP IIb/IIIa inhibitor and the group receiving bivalirudin plus a GP IIb/IIIa inhibitor. However, compared with those receiving UFH plus a GP IIb/IIIa inhibitor, the 30-day composite of ischemia or major bleeding was significantly lower for those receiving bivalirudin alone. This difference was attributed to reduced major bleeding with bivalirudin.

How Effective are Antithrombotic Therapies in Primary Percutaneous Coronary Intervention (HEAT-PPCI) trial was a head-to-head comparison of bivalirudin versus UFH.[73] Patients who underwent emergent PCI were randomly assigned to receive either UFH or bivalirudin. At 28 days, the primary efficacy outcome of one or more MACE was significantly lower in the UFH group. When the individual components were evaluated, there was no difference in

all-cause mortality or cerebrovascular accident. The driving factors favoring heparin were new MI or reinfarction and additional unplanned target lesion revascularization. The majority of these cases were related to stent thrombosis in the bivalirudin group (0.9% vs 3.4%, *P* = .001). Major and minor bleeding events did not differ between the two groups.

Because J.W. is receiving an invasive strategy for his NSTE-ACS and he has adequate renal function, enoxaparin, UFH, or bivalirudin could be initiated and continued until the end of PCI.

Antithrombotic Therapy

Case 13-2, Question 3: What oral antithrombotic medications should be considered for J.W.?

For both ischemia-guided and invasive strategies, aspirin along with a $P2Y_{12}$ inhibitor (loading with maintenance dose) should be added as soon as possible to anticoagulant therapy unless the patient is to proceed to CABG. For an invasive strategy, prasugrel or ticagrelor can be considered in lieu of clopidogrel. The 2014 ACC/AHA guidelines recommend ticagrelor as the preferred agent (Class IIa). Prasugrel should only be used in patients undergoing PCI as long as they are not at high risk for bleeding complications.[1]

The use of clopidogrel in NSTE-ACS was evaluated in two studies.[74,75] In the *C*lopidogrel in *U*nstable angina to prevent *R*ecurrent ischemic *E*vents (CURE) trial, patients with NSTE-ACS were randomized to placebo plus aspirin (75–325 mg) or clopidogrel (300 mg, immediately followed by 75 mg daily) plus aspirin.[74] The composite of cardiovascular death, MI, or stroke was significantly reduced with clopidogrel. However, compared with placebo, an increase in major and minor bleeding was seen. On the basis of these data, clopidogrel with aspirin should be administered immediately on admission and continued ideally for 1 year in patients with ACS.[1]

The PCI–*CL*opidogrel as *A*djunctive *R*eperfus*I*on *T*herap*Y* (PCI-CLARITY) study was a planned subanalysis (*N* = 1863) of the *CL*opidogrel as *A*djunctive *R*eperfus*I*on *T*herap*Y*–Thrombolysis in Myocardial Infarction (CLARITY-TIMI) 28 study (see Case 13-1, Question 8) that evaluated the effects of pretreatment with aspirin plus clopidogrel, compared with aspirin plus placebo, in patients undergoing PCI with coronary artery stenting.[76] Compared with placebo, pretreatment with clopidogrel significantly reduced the incidence of cardiovascular death, MI, or stroke as well as recurrent MI or stroke before PCI with no significant excess in TIMI major or minor bleeding.

Case 13-2, Question 4: What loading dose should J.W. receive and when should he receive it? What about his maintenance dose?

A loading dose of 600 mg of clopidogrel in patients undergoing PCI achieves greater platelet inhibition with fewer low responders and decreases the incidence of major cardiac events compared with a loading dose of 300 mg.[1] A 300-mg clopidogrel loading dose provides adequate antiplatelet activity in 6 hours, whereas a 600-mg clopidogrel loading dose provides antiplatelet activity in 2 hours. Even after a loading dose, clopidogrel requires several hours to be metabolized to its active metabolite. The current guidelines prefer 600 mg owing to a greater, more rapid and more consistent degree of platelet inhibition. Patients undergoing PCI who have previously received a loading dose of 300 mg of clopidogrel and are on a 75-mg daily maintenance dose should receive another 300-mg loading dose. Data do not exist on additional loading doses for patients currently receiving maintenance doses of prasugrel or ticagrelor.

Prasugrel has been evaluated in patients with ACS undergoing PCI. In the Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition with Prasugrel–Thrombolysis in Myocardial Infarction (TRITON-TIMI) 38 study, patients with moderate- to high-risk ACS, 26% of whom had STEMI, were randomized to prasugrel (60-mg loading dose followed by 10 mg

daily) or clopidogrel (300-mg loading dose followed by 75 mg daily).[77] All patients received aspirin (75–162 mg daily). The primary outcome of death from cardiovascular causes, nonfatal MI, or nonfatal stroke occurred in 9.9% of patients receiving prasugrel and 12.1% of patients taking clopidogrel ($P < .001$). However, prasugrel was associated with a significant increase in TIMI major, fatal, and life-threatening bleeding. A post hoc analysis found three subgroups that did not benefit from prasugrel: patients with a history of stroke or transient ischemic attack (TIA), age 75 years and older, or body weight <132.28 pounds (60 kg). Patients with at least one of these risk factors exhibited a higher rate of bleeding.[78] The U.S. Food and Drug Administration (FDA) recommends that a 5-mg (rather than a 10-mg) maintenance dose be considered for those patients weighing <132.28 pounds (60 kg), even though this dose has not been studied.[79]

In the *PLAT*elet inhibition and patient *O*utcomes (PLATO) trial, patients with ACS, with or without ST-segment elevation were randomized to receive ticagrelor (180-mg loading dose, 90 mg twice daily thereafter) or clopidogrel (300–600-mg loading dose, then 75 mg daily). Compared to clopidogrel, ticagrelor demonstrated a 16% reduced rate of mortality from MI, vascular causes, or stroke ($P < .001$) without an increase in the rate of major bleeding but an increased rate in CABG-related bleeding ($P = .03$).[80] However, the lowest 1-year rates of cardiovascular death, MI, or stroke were noted in patients with ACS treated with ticagrelor and maintenance low-dose aspirin (≤100 mg/day), whereas the highest rates occurred in those treated with ticagrelor and high-dose aspirin (>300 mg/day).[81] Based on these data, the maintenance dose of aspirin should not exceed 100 mg/day.[82]

When compared with clopidogrel, prasugrel and ticagrelor are more potent, exhibit a lower incidence of stent thrombosis, have fewer drug–drug interactions, and lack variable response based on pharmacogenomics (refer to Chapter 12, Chronic Stable Angina, about responders and nonresponders to clopidogrel). However, many providers have been concerned with the higher risk of bleeding. In the case of J.W., clopidogrel, prasugrel, or ticagrelor

could be added because he does not have a contraindication to any of these drugs. Ticagrelor may be preferred as long as cost is not a concern for the patient.

After PCI with coronary stent deployment with either a drug-eluting stent (DES) or a bare-metal stent, clopidogrel 75 mg, prasugrel 5 to 10 mg, or ticagrelor 90 mg twice daily should be administered for at least 12 months. It is important to highlight that clopidogrel and ticagrelor should be discontinued for 5 days and prasugrel for 7 days before surgery.

Because a rapid onset of action is needed, J.W. should receive a loading dose of 600 mg of clopidogrel as soon as possible, followed by 75 mg daily for at least 12 months. If prasugrel is chosen, a loading dose of 60 mg would be given followed by 10 mg daily as long as the patient is >132.28 pounds (60 kg). For ticagrelor, a loading dose of 180 mg is recommended followed by 90 mg twice daily. Aspirin 81 mg daily should be continued indefinitely.

Case 13-2, Question 5: Should a GP IIb/IIIa inhibitor be added? If so, which one?

In patients with NSTE-ACS, the GP IIb/IIIa inhibitors are of benefit for patients with high-risk features undergoing an early invasive strategy.[1] Analysis of GP IIb/IIIa studies suggests that those patients who obtain the greatest advantage from these agents are those who have elevated troponins, diabetes, ST-segment changes, high thrombus burden, or a TIMI risk score of ≥4 at presentation. The guidelines recommend that for patients with NSTE-ACS who will be treated initially according to an early invasive strategy, either a GP IIb/IIIa inhibitor or a $P2Y_{12}$ inhibitor (clopidogrel or ticagrelor) should be added to aspirin and anticoagulant therapy before diagnostic angiography is performed.[1] The GP IIb/IIIa inhibitors tirofiban or eptifibatide are generally given for 18 to 72 hours.[1] Intracoronary administration of a GP IIb/IIIa inhibitor may be appropriate in some patients. Compared to IV, the higher local concentration achieved via intracoronary administration may result in a higher rate of thrombus

resolution and lower bleeding risk. At this time, additional trials are needed to identify the role of intracoronary use of GP IIb/IIIa inhibitors in the contemporary treatment of patients with ACS.

The guidelines recommend that in the setting of DAPT used with UFH, the adjunctive use of a GP IIb/IIIa inhibitor administered at the time of PCI cannot be recommended as routine therapy. However, a GP IIb/IIIa inhibitor may be beneficial in those with a large thrombus burden or those who have not received adequate $P2Y_{12}$ inhibitor loading.[1]

J.W. has a TIMI risk score of 4; therefore, the addition of eptifibatide or tirofiban is a reasonable choice if a large thrombus burden is demonstrated on angiography. Administration before PCI ("upstream") is not indicated unless the administration of a $P2Y_{12}$ inhibitor is delayed until the time of PCI. Platelets and signs and symptoms of bleeding should be monitored closely.

Because J.W. is not at high risk for bleeding, DAPT in addition to UFH should be adequate therapy. If a large thrombus burden is demonstrated on angiography, a GP IIa/IIIb could be initiated during PCI.

If J.W. had not received an oral $P2Y_{12}$ inhibitor or a GP IIb/IIIa inhibitor, consideration could be given to administering IV cangrelor, a direct-acting $P2Y_{12}$ inhibitor, before PCI. Based on the results of the CHAMPION-PHOENIX trial, cangrelor could be administered as a 30 µg/kg bolus followed by a 4 µg/kg/minute IV infusion for at least 2 hours or for the duration of the PCI.[30] After discontinuation of the infusion, an oral $P2Y_{12}$ inhibitor should be administered (ticagrelor 180-mg load during or upon immediate discontinuation of infusion; prasugrel 60 mg or clopidogrel 600 mg upon immediate discontinuation of infusion) followed by aspirin 81 mg daily along with a maintenance dose of the $P2Y_{12}$ inhibitor. If clopidogrel or prasugrel is administered during the infusion, they will have no antiplatelet effect until the next dose is administered.

CASE 13-2, QUESTION 6: What if an ischemia-driven strategy was decided for J.W. instead, would his antithrombotic therapy change?

Management Strategy

Ischemia-Guided Strategy

An ischemia-guided strategy avoids early invasive procedures, instead of relying on the patient's symptoms to direct the need for intervention. Similarly, J.W. would be optimized on anti-ischemic and antithrombotic regimens. At this time, prasugrel and bivalirudin are only indicated in patients undergoing PCI. In addition, the bleeding risk of GP IIb/IIIa inhibitors outweighs the benefit in this approach, and, therefore, these medications should only be used if PCI is pursued. If during his hospitalization, the patient were to experience any recurrent ischemia, refractory angina despite medical therapy, or high-risk features (eg, arrhythmias, signs or symptoms of HF, hemodynamic instability, elevated cardiac enzymes), an invasive approach would be pursued.[1]

LONG-TERM THERAPY

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers, and Direct Renin Inhibitors

CASE 13-3

QUESTION 1: J.S. is a 68-year-old male who presents with an NSTEMI along with signs and symptoms of HF. His past medical history includes hypertension treated with hydrochlorothiazide 25 mg daily and diabetes for which he takes metformin 500 mg twice daily. He has smoked a pack of cigarettes per day for the past 40 years. On admission, his BP was 144/86 mm Hg and his heart rate was 90 beats/minute. His weight is 200.62 pounds (91 kg), with a height of 69 inches (175.26 cm), and a body mass index (BMI) of 29.5 kg/m^2. Laboratory values include the following:

Na^+, 139 mEq/L
K^+, 4.2 mEq/L
Cl^-, 100 mEq/L
CO_2, 20 mEq/L
BUN, 15 mg/dL
SCr, 1.3 mg/dL (creatinine clearance [CrCl] ~60 mL/minute)
Glucose, 130 mg/dL
Hemoglobin A_{1c}, 7.5%
Mg, 2 mEq/L
Troponin I-Ultra, 10 ng/mL (normal, <0.02 ng/mL)

He is administered aspirin 325 mg, prasugrel 60 mg, IV NTG infusion, enoxaparin, and intranasal oxygen. J.S. is immediately sent to the catheterization laboratory where he receives a DES in his left anterior descending artery. After stabilization of his HF symptoms, J.S. is started on oral metoprolol tartrate 25 mg every 6 hours. An echocardiogram is performed before discharge and shows an LVEF of 35%. On the day before discharge, J.S. develops new-onset atrial fibrillation.

Is an ACE inhibitor appropriate for J.S.? When should an ARB be considered?

After an AMI, the heart undergoes processes that initially compensate for the loss of contractile function but may increase the long-term risk for the development of HF. This is referred to as *remodeling* of the ventricle (see Chapter 14, Heart Failure). The increase in the number of survivors of AMI has led to an increase in the number of patients with HF. A number of clinical trials that used ACE inhibitors have demonstrated reductions in HF symptoms and mortality after MI.[5]

For patients with ACS, oral ACE inhibitor therapy should be started within the first 24 hours of presentation for those with an LVEF of ≤40% (even if asymptomatic) or clinical evidence of HF. In addition, ACE inhibitors should also be considered for patients with concomitant hypertension, diabetes, and/or chronic kidney disease.[5] The use of IV ACE inhibitor therapy is not recommended. Owing to its short half-life, captopril could be given early in the hospitalization, beginning with a test dose of 6.25 mg and then titrated as tolerated. Once it is established that the patient can tolerate an ACE inhibitor, he or she can be switched to a once-daily agent such as lisinopril to

simplify the regimen. The BP should be monitored closely, with systolic BP maintained >90 mm Hg. Renal function and serum potassium levels should be monitored closely during the first few months of therapy. Because J.S. presents with clinical symptoms of HF, he is a candidate for an ACE inhibitor. In addition, J.S. has an EF of <40%, hypertension, and diabetes; therefore, the ACE inhibitor should be continued indefinitely (see Table 13-2).

If the patient cannot tolerate an ACE inhibitor because of cough, an ARB may be an alternative. In the *OP*timal *T*herapy *I*n *M*yocardial infarction with the *A*ngiotensin II *A*ntagonist *L*osartan (OPTIMAAL) trial and *VAL*sartan *I*n *A*cute myocardial i*N*farc*T*ion (VALIANT) trial, losartan and valsartan demonstrated reductions that were similar in all-cause mortality compared with captopril.[83,84] Dual therapy of ACE inhibitors with ARBs offers no additional benefits, but increases side effects. At this time, an angiotensin receptor–neprilysin inhibitor (ARNI) is indicated to reduce the risk of cardiovascular death and hospitalization for chronic HF.[85] Current guidelines suggest the use of an ARNI in patients with chronic symptomatic heart failure with reduced ejection fraction (HFrEF) who have tolerated an ACE inhibitor or ARB.[86] Since the publication of the 2017 guidelines, additional clinical studies coupled with clinical experience do support an option to initiate an ARNI de novo; however, patients should be closely monitored for tolerability specifically assessing BP, electrolytes, and renal function as well as occurrence of angioedema.[87]

Aldosterone Antagonists

Case 13-3, Question 2: Should J.S. receive an aldosterone antagonist?

As with angiotensin II, aldosterone plays an important role in LV remodeling. Inhibiting aldosterone directly in addition to ACE inhibitor therapy was first evaluated in patients with HF in the *R*andomized *AL*dactone *E*valuation *S*tudy (RALES) (see Chapter 14, Heart

Failure). Another aldosterone antagonist, eplerenone, is a selective inhibitor of the mineralocorticoid receptor with fewer sexual side effects. In the EPHESUS, patients with AMI and EF <40% receiving optimal medical therapy were randomized to eplerenone or placebo.[37] Significant reductions in mortality (15%), sudden death (13%), and cardiovascular death or hospitalization (21%) were seen with eplerenone compared to placebo.

The ACC/AHA guidelines recommend an aldosterone antagonist in patients with NSTE-ACS or STEMI who are already receiving therapeutic doses of an ACE inhibitor, have an EF <40%, and have either symptomatic HF or diabetes.[1,5] Potential contraindications to the use of an aldosterone antagonist in this setting include significant renal dysfunction (creatinine >2.5 mg/dL in males, >2.0 mg/dL in females, or CrCl <30 mL/minute) or hyperkalemia (potassium > 5 mEq/L).

Because J.S. has symptomatic HF with an EF <40% and diabetes, he is a candidate for an aldosterone antagonist. Serum potassium and renal function need to be checked in 2 to 3 days and 1 week after therapy initiation, then every month for the first 3 months. ACE inhibitor and potassium supplement doses may need to be adjusted.[86,87]

a-Blockers

Case 13-3, Question 3: Should J.S. receive a β-blocker on discharge?

The ACC/AHA guidelines recommend continued β-blocker therapy at discharge for all patients after ACS.[1,5] The benefits of β-blockers in reducing reinfarction and mortality outweigh the risk, even in patients with stable bronchospastic disease, depression, insulin-dependent diabetes, severe peripheral vascular disease, first-degree heart block, and moderate LV dysfunction. Metoprolol succinate, carvedilol, and bisoprolol are considered first-line choices in patients with HF, whereas selective β_1-blockers should be considered in

patients with chronic obstructive pulmonary disease (COPD). For patients with asthma, selective β_1-blockers may be considered once the relative risks and benefits are considered. Being discharged on a β-blocker is a quality performance measure.[88] However, debate exists surrounding the duration of use, especially in low-risk patients without compelling indications.[89–92] Data suggest that the benefits from β-blockers emerge early following an AMI and are maintained out to 1 year. Although the exact duration of benefit is unknown, high-risk patients (eg, GRACE score ≥121 and diuretic use) are likely to continue to derive benefit for up to 3 years. The 2011 AHA/ACCF (American College of Cardiology Foundation) secondary prevention guidelines recommend a 3-year treatment course for patients with normal LV function, with an option to continue indefinitely as long as the medication is well tolerated. Because J.S. has a low EF, he should be transitioned from oral metoprolol tartrate to metoprolol succinate, carvedilol, or bisoprolol, which should be continued indefinitely.

Sodium–Glucose-Linked Cotransporter-2 Inhibitors

Case 13-3, Question 4: Should J.S. be started on a sodium–glucose- linked cotransporter-2 (SGLT2) inhibitor?

SGLT2 inhibitors not only lower plasma glucose concentrations through increased urinary glucose excretion, but they also mediate osmotic diuresis and natriuresis to lower preload, pulmonary congestion, and edema. In addition, SGLT2 inhibitors exert pleiotropic effects and provide direct cardioprotective and nephroprotective effects by reducing inflammation, oxidative stress, and fibrosis.[93] Given that J.S. has underlying diabetes with new evidence of HF, the 2022 Standards of Medical Care in Diabetes would recommend use of an SGLT2 inhibitor (eg, empagliflozin, canagliflozin, dapagliflozin) in addition to metformin.[94] Clinical trials

have demonstrated a reduction in the risk of cardiovascular death and/or major cardiovascular events in adults with type 2 diabetes mellitus and established cardiovascular disease. In addition, evidence also suggests robust effects on reducing the risk of hospitalization for HF.[95–97] Most recently, SGLT2 inhibitors have an emerging role in HF care in patients without diabetes.[98,99] Dapagliflozin and empagliflozin have an approved indication for HF.

Given a recent A_{1c} of 7.5% and new evidence of HF, J.S. should be started on an SGLT2 inhibitor. Upon initiation, the diuretic dose many need to be adjusted depending on clinical status with close monitoring to assess renal function and volume status.

Lipid-Lowering Agents

Case 13-3, Question 5: Should J.S. be started on a lipid-lowering agent? If so, which one? When should it be initiated?

A complete fasting lipid profile would be helpful and should be completed within 24 hours of presenting with an AMI.[1,5] This is often overlooked or not done because the patient is not fasting. Most patients will require a low-cholesterol, low-saturated fat diet in addition to lipid-lowering therapy. The ACC/AHA STEMI and NSTE-ACS guidelines recommend that a high-intensity statin be initiated or continued in all patients with ACS unless contraindications are present.[1,5] This would consist of atorvastatin 40 to 80 mg or rosuvastatin 20 to 40 mg daily.[35] When triglycerides are 500 mg/dL or more, drug therapy with niacin or a fibrate is beneficial.[92]

The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) trial evaluated patients with NSTE-ACS receiving atorvastatin 80 mg/day or placebo within 24 to 96 hours of hospitalization. A significantly lower rate of death and nonfatal major cardiac events at 4-month follow-up was seen in patients receiving atorvastatin.[100] In the *PR*avastatin *O*r Ator*V*astatin *E*valuation and *I*nfection *T*herapy (PROVE IT)-TIMI 22 trial, patients with ACS who

received atorvastatin 80 mg/day for 10 days exhibited a significantly lower risk of death, MI, UA hospitalization, stroke, and revascularization when compared with those on pravastatin 40 mg/day.[100] The A to Z trial showed a favorable trend toward major cardiovascular event reduction in patients with AMI receiving an intensive simvastatin regimen (40 mg/day for 1 month followed by 80 mg/day thereafter) when initiated within 12 hours of stabilization compared to a less intensive regimen (placebo for 4 months followed by simvastatin 20 mg/day).[101] However, based on clinical trials, observational studies, adverse event reports, and prescription use data, simvastatin 80 mg may be associated with increased muscle injury (refer to Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease).[35]

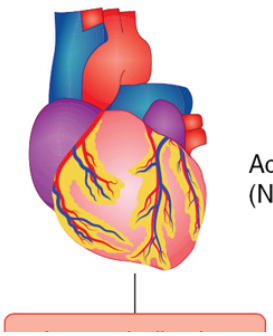
In the case of J.S., he should receive a high-intensity statin within 24 hours of his hospitalization and be discharged on a statin regardless of LDL cholesterol. This is a quality core performance measure.[88] Drug interactions, patient tolerability, and affordability should be considered. Currently, the goal LDL for patients with ACS remains controversial. The ACC/AHA guidelines do not recommend a specific goal LDL.[1,5,35] However, the National Lipid Association does recommend a goal LDL <70 mg/dL in patients with ACS.[102] For J.S., it would be reasonable to begin atorvastatin 80 mg daily and obtain an LDL reduction of ≥50%.

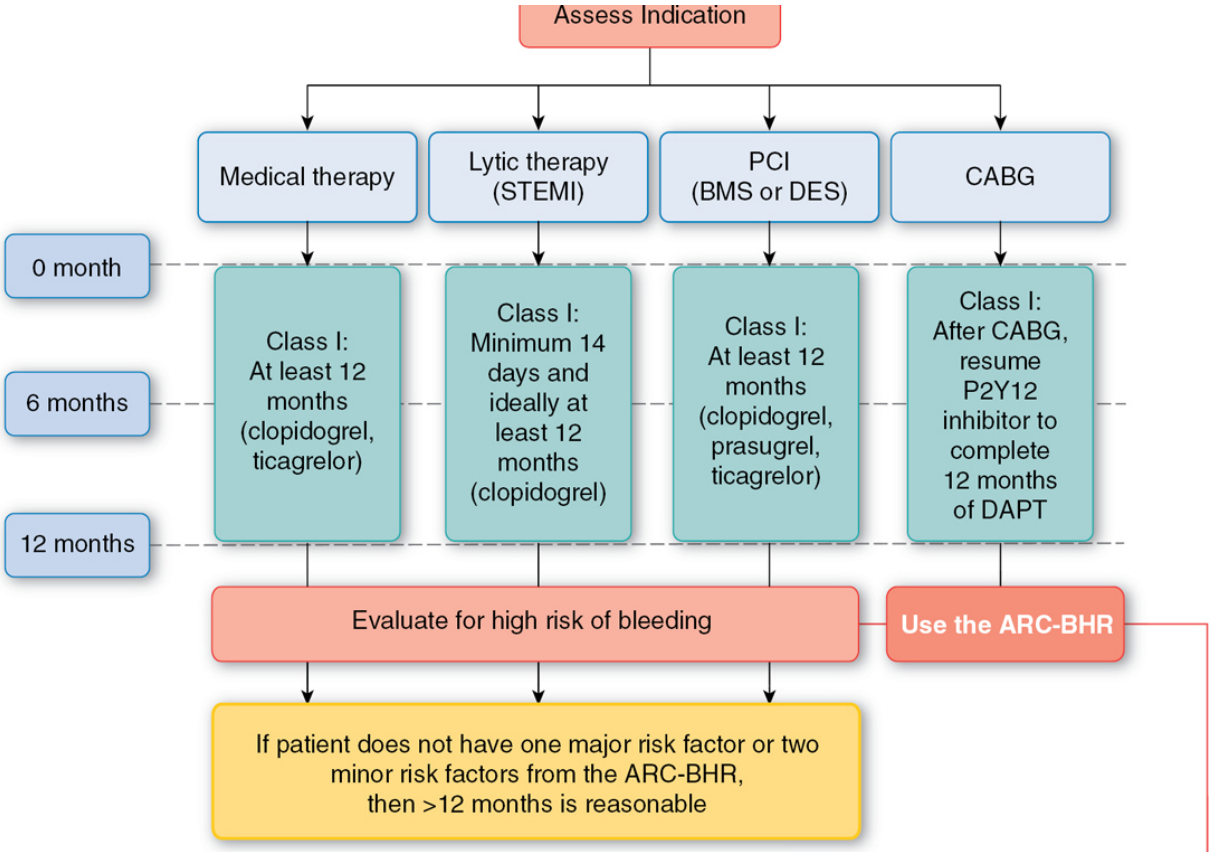
Antiplatelet Therapy

Case 13-3, Question 6: How long should J.S. continue his aspirin and prasugrel?

Antiplatelet therapy with aspirin should be lifelong for J.S. because of aspirin's beneficial effects on reinfarction. There appears to be no difference in efficacy for a wide range of aspirin doses (75–1500 mg/day), although higher doses may increase the incidence of side effects. The ACC/AHA guidelines recommend a dose of 81 to 325 mg daily indefinitely, with a preferred maintenance dose of 81 mg

daily.[1,5,103] DAPT with clopidogrel or ticagrelor, or prasugrel and with aspirin, compared with aspirin alone, reduces major cardiovascular events in patients with established ischemic heart disease.[103–105] The use of DAPT with a $P2Y_{12}$ inhibitor for patients who have undergone coronary stenting reduces the risk of future stent thrombosis.[1,5,103] In patients with ACS, the 2016 ACC/AHA guidelines recommend that, ideally, the $P2Y_{12}$ inhibitor should be continued for at least 1 year regardless of the type of coronary stent (**Fig. 13-6**).[106] Nonetheless, the duration of DAPT following PCI continues to evolve. Several randomized clinical trials have studied varying durations of DAPT to identify optimal therapy duration (**Table 13-5**). In a pooled analysis of 33,051 patients with either ACS or stable CAD undergoing PCI and received a newer generation DES, Britl et al found that compared with 3 to 6 months of DAPT, 12 months of DAPT was associated with no difference in all-cause mortality, major hemorrhage, or stent thrombosis.[107] Compared with 6 to 12 months of DAPT, 18 to 48 months of DAPT was associated with no difference in all-cause mortality but was associated with lower rates of MI and stent thrombosis. However, compared with 6 to 12 months of DAPT, 18 to 48 months was also associated with increased major bleeding. Prolonged DAPT of 18 to 48 months was associated with three fewer stent thromboses, six fewer MIs, and five more major bleeding episodes per 1000 patients. Based on these data, early discontinuation of antiplatelet therapy may be considered after 6 months if bleeding risk is high and antiplatelet therapy should be continued for >12 months if bleeding risk is low.[107] Academic Research Consortium Major and Minor-High Bleeding Risk (ARC-HBR) Criterion (**Fig. 13-6**).[12]





Academic Research Consortium Major and Minor Criterion for High Bleeding Risk (ARC-BHR)

Major	Minor
Anticipated long term use of anticoagulation	Long term use of oral NSAIDs and/or steroids
Severe or end-stage CKD (eGFR <30 mL/minute)	Moderate CKD (eGFR 30–59 mL/minute)
Hemoglobin <11 g/dL	Hemoglobin 11–12.9 g/dL for men and 11–11.9 g/dL for women
Spontaneous bleeding requiring hospitalization or transfusion in the past 6 months or at any time if recurrent	Spontaneous bleeding requiring hospitalization or transfusion in the past 12 months not meeting major criterion
Moderate or severe baseline thrombocytopenia (platelet count <100 × 10^9/L)	Age ≥75 years
Chronic bleeding diathesis	Any ischemic stroke at any time not meeting major criterion
Liver cirrhosis with portal hypertension	
Active malignancy (excluding nonmelanoma skin cancer) within the past 12 months	
Previous spontaneous intracranial hemorrhage	
Previous traumatic intracranial hemorrhage within the past 12 months	
Presence of brain AVM	
Moderate or severe ischemic stroke (NIHSS score ≥5) in past 6 months	
Nondeferrable major surgery on DAPT	
Recent major surgery or major trauma within 30 days before PCI	

Figure 13-6 Treatment algorithm for duration of $P2Y_{12}$ inhibitor therapy in patients with ACS with DAPT. ARC-HBR, Academic Research Consortium Major and Minor Criterion for High Bleeding Risk; ACS, acute coronary syndrome; AVM, arteriovenous malformation; BMS, bare-metal stent; CABG, coronary artery bypass graft; DAPT, dual antiplatelet therapy; DES, drug-eluting stent; lytic, fibrinolytic therapy; eGFR, estimated glomerular filtration rate; NSAIDS, nonsteroidal anti-inflammatory drugs; NSTE-ACS, non–ST-elevation acute coronary syndrome; NSTEMI, non–ST segment elevation myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST segment elevation myocardial infarction. Table 13-5
Summary of Major Trials Evaluating Length of DAPT Therapy

and Outcomes

Trial (Year)	DAPT Treatment Strategy	DAPT Duration (months)	N/ACS (%)	Trial Design	Primary End Point	Primary End Point Result/Major Bleeding
Standard, Extended, or No PY_{12} Inhibitor						
RESET (2012)	Clopidogrel + ASA	3 vs 12	2117 (55)	Open-label noninferiority	Cardiac death, MI, ST, revascularization, or bleeding at 1 year	4.7% vs 4.7% (P_{NI} <.001) 0.2% vs 0.6 % (P = .16)
OPTIMIZE (2013)	Clopidogrel + ASA	3 vs 12	3119 (32)	Single-blind, noninferiority	All-cause death, MI, stroke, or bleeding at 1 year	6.0% vs 5.8% (P_{NI} = .002) 0.6% vs 0.9% (P = .41)
REDUCE (2019)	Prasugrel (10.4%), ticagrelor (49.8%), or clopidogrel (40.8%) + ASA	3 vs 12	1496 (100)	Open-label, noninferiority	All-cause death, MI, ST , stroke, TVR, or bleeding at 1 year	8.2% vs 8.4% (P_{NI} < .001) 3.3% vs 4.0%, (P = .46)
EXCELLENT (2012)	Clopidogrel + ASA	6 vs 12	1443 (51)	Open-label, noninferiority	Cardiac death, MI, or ischemia-driven TVR at 1 year	4.8% vs 4.3% (P_{NI} = .001) 0.3% vs 0.6% (P = .42)
ISAR-SAFE (2015)	Clopidogrel + ASA	6 vs 12	4000 (40)	Double-blind, noninferiority	All-cause death, MI, ST, stroke, and TIMI major bleeding at 9 months	1.5% vs 1.6% (P_{NI} <.001) 0.2% vs 0.3% (P = .64)
I-LOVE-IT-2 (2016)	Clopidogrel +ASA	6 vs 12	1829 (85)	Single-blind, noninferiority	Cardiac death, target vessel MI or clinically indicated TLR at 1 year	6.8% vs 5.9% (P_{NI} = .0065) 1.3% vs 0.8% (p = .17)
IVSU-XPL (2016)	Clopidogrel + ASA	6 vs 12	1400 (49)	Open-label, superiority	Cardiac death, MI, stroke, or TIMI major bleeding at 1 year	2.1% vs 2.2% (P = .85) 0.7% vs 1.0% (P = .56)
OPTIMA-C (2018)	Clopidogrel + ASA	6 vs 12	1368 (50)	Open-label, noninferiority	Cardiac death, MI, ischemia-driven TVR at 1 year	1.2% vs 0.6%, (P_{NI} = .05)
DAPT STEMI (2018)	Prasugrel (29%), ticagrelor (29%), or clopidogrel (42%) + ASA	6 vs 12	870 (100)	Single-blind, noninferiority	All-cause mortality, revascularization, MI, stroke, and TIMI major bleeding at 18 months	4.8% vs 6.6% (P_{NI} = .004) 3.2% vs 4.3% (P = .40)
SMART-DATE (2018)	Clopidogrel + ASA	6 vs 12	2172 (100)	Single-blind, noninferiority	All-cause death, MI, or stroke at 18 months	4.7% vs 4.2% (P_{NI} = .03) 0.5% vs 0.8% (P = .33)
NIPPON (2017)	Clopidogrel (97.1%) or ticlopidine (2.7%) or prasugrel (0.2%) + ASA	6 vs 18	3773 (33)	Open-label, noninferiority	All-cause death, MI, stroke, and major bleeding at 18 months	2.1% vs 1.5% (P_{NI} < .05) 0.7% vs 0.7% (P = .99)
PRODIGY (2012)	Clopidogrel + ASA	6 vs 24	1970 (75)	Open-label, superiority	All-cause death, MI, or stroke at 2 years	10.0% vs 10.1% (P = .91) 0.6% vs 1.5% (P = .041)
ITALIC (2017)	Clopidogrel + ASA	6 vs 24	1850 (44)	Open-label, noninferiority	All-cause death, MI, urgent TVR, stroke, or major bleeding at 1 year	1.6% vs 1.5% (P_{NI} = .0002) 0.0% vs 0.4% (P = N/A)
ARTIC-Interruption (2014)	Clopidogrel (91%) or prasugrel (9%) + ASA	12 vs 18–30	1259 (26)	Open-label, superiority	All-cause death, MI, ST, stroke, or urgent revascularization at 18 months	0.4% vs 0.4% (P = .58) 0.5% vs 1% (P = .07)
DAPT (2014)	Clopidogrel (65%) or prasugrel (35%) + ASA	12 vs 30	9961 (43)	Double-blind, superiority	All-cause death, MI, or stroke at 30 months	5.9% vs 4.3% (P <.001) 1.6% vs 2.5% (P = .001)
DES LATE (2014)	Clopidogrel + ASA	12 vs 36	5045 (61)	Open-label, superiority	Cardiac death, MI, or stroke at 2 years	2.6% vs 2.4% (P = .75) 1.4% vs 1.1% (P = .20)
OPTIDUAL (2015)	Clopidogrel + ASA	12 vs 48	1385 (36)	Open-label, superiority	All-cause death, MI, stroke, or major bleeding at 3 years	7.5% vs 5.8% (P = .17) 2.0% vs 2.0% (P = .95)
PEGASUS TIMI 54 (2016)	Ticagrelor + ASA	0 vs 33	21,162 (100)	Double-blind, superiority	Cardiac death, MI, or stroke at 3 years	7.8% vs 9.0% (P = .001) 2.6% vs 1.1% (P < .001)
Aspirin Discontinuation						
Trial	**DAPT Treatment Strategy**	**ASA duration**	**N/ACS (%)**	**Trial Design**	**Primary End Point**	**Primary End Point Result/Major Bleeding**
GLOBAL LEADERS (2018)	DAPT (ticagrelor/ASA) for 1 month, followed by ticagrelor for 23 months vs DAPT (clopidogrel/ASA for stable coronary disease or aspirin/ticagrelor for unstable coronary disease) for 12 months, followed by ASA for 12 months	1 vs 12	15,968 (47)	Open-label, superiority	All-cause death or new Q-wave MI at 2 years	3.8% vs 4.4% (P = .07) 2.0% vs 2.1% (P = .77)
STOPDAPT-2 (2019)	DAPT (clopidogrel + ASA) for 1 month followed by clopidogrel monotherapy for 11 vs 12 months of DAPT	1 vs 12	3045 (38)	Open-label, noninferiority	Cardiac death, MI, stroke, ST, and TIMI major or minor bleeding at 1 year	2.4% vs 3.7% (P_{NI} < .001) 0.4% vs 1.5% (P = .004)
SMART-CHOICE (2019)	DAPT for 3 months followed by $P2Y_{12}$ inhibitor for 9 months vs DAPT for 12 months	3 vs 12	2993 (58)	Open-label, noninferiority	All-cause death, MI, or stroke at 1 year	2.9% vs 2.5% (P_{NI} = .007) 2.0% vs 3.4% (P = .02)
TICO (2020)	DAPT (ticagrelor + ASA) for 3 months followed by ticagrelor for 9 months vs DAPT for 12 months	3 vs 12	3056 (100)	Open-label, superiority	All-cause death, MI, ST, stroke, TVR, or TIMI major bleeding at 1 year	3.9% vs 5.9% (P = .01) 1.7% vs 3.0% (P = .02)
TWILIGHT (2019)	DAPT (ticagrelor + ASA) for 3 months followed by ticagrelor for 9 months vs DAPT for 12 months	3 vs 12	7119 (65%)	Open-label, superiority	BARC type 2, 3, or 5 bleeding at 1 year	4.0% vs 7.1% (P < .001)

ACS, acute coronary syndrome; ASA, aspirin; ARTIC-Interruption, assessment by a double randomisation of a conventional antiplatelet strategy versus a monitoring-guided strategy for drug-eluting stent implantation and, of Treatment Interruption versus Continuation 1 year after stenting; BARC, Bleeding Academic Research

Among patients treated with DAPT after PCI, recent trials have tested whether stopping aspirin instead of the $P2Y_{12}$ inhibitor improved outcomes (**Table 13-5**). A meta-analysis of the major randomized trials studying $P2Y_{12}$ inhibitor monotherapy after a short-term DAPT of 1 to 3 months demonstrated that this strategy was

associated with a 40% reduction in major bleeding ($P < .01$) without an associated increase in MACE, MI, or death compared with standard 12 months of DAPT.[108] These findings were consistent in the subset of patients who underwent PCI for ACS. Based on these trials, discontinuing aspirin after DAPT and continuing only the $P2Y_{12}$ inhibitor may be associated with better outcomes in patients with ACS.

Data from the DAPT trial found that DAPT with clopidogrel or prasugrel continued for 30 months after placement of a DES significantly reduced the risk of stent thrombosis and MACE compared with 12 months of therapy but were associated with an increased risk of bleeding.[109]

Because J.S. underwent PCI following his NSTEMI and received a coronary stent, a conservative approach would be to continue his aspirin 81 mg daily indefinitely. He should continue prasugrel 10 mg daily for at least 1 year. Aspirin should be prescribed at hospital discharge because it is a quality performance measure.[88] Based on the ARC-HBR criterion, J.S. does not have a high risk of bleeding; thus, based on clinical judgment and thrombosis risk, he could continue prasugrel for up to 48 months.

Oral Anticoagulation

Case 13-3, Question 7: Given the development in new-onset atrial fibrillation, is oral anticoagulation indicated for J.S. at this time?

Certain patients, particularly those with atrial fibrillation at increased risk for stroke, may have a need to add oral anticoagulation to DAPT. Data suggest that ~10% of patients with recent PCI have concomitant atrial fibrillation and up to 2% to 22% of patients may develop atrial fibrillation following an AMI.[110] Similarly, venous thromboembolism or development of an LV thrombus may warrant an indication for triple therapy (eg, aspirin, a $P2Y_{12}$ inhibitor, and oral anticoagulation). Given the significant concern for bleeding

with a two- to threefold increased risk for patients on triple therapy, clinical judgment is needed to decide whether the benefit is likely to exceed the risk.

Direct oral anticoagulants (DOACs; eg, apixaban, rivaroxaban, dabigatran, edoxaban) are typically recommended first line for patients with atrial fibrillation and venous thromboembolism, whereas warfarin is preferred for valvular heart disease. In patients with ACS and a need for oral anticoagulation, the ACC expert consensus pathway recommends DOACs in preference over warfarin because of lower risk of bleeding, simplified dosing, rapid onset of action, and lack of bridging. Furthermore, careful selection of the most appropriate $P2Y_{12}$ inhibitor is important and preference for clopidogrel should be considered.[110] Prasugrel and ticagrelor can produce a greater degree of platelet inhibition than clopidogrel and are associated with greater rates of bleeding. If a newer agent is warranted, ticagrelor would be favored over prasugrel.[110] For patients on warfarin, consideration can be given to targeting a goal international normalized ratio (INR) of 2.0 to 2.5 for those patients whose usual goal INR is between 2.0 to 3.0; however, no prospective studies have demonstrated that a target INR of 2.0 to 2.5 reduces bleeding complications.[1,5] Current ACC/AHA guidelines for the management of atrial fibrillation recommend that if triple therapy is used, the duration should be limited with consideration for discontinuation of aspirin after 4 to 6 weeks to minimize the risk of bleeding.[111] In the *W*hat is the *O*ptimal antiplat*E*let and anticoagulant therapy in patients with oral anticoagulation and coronary *S*ten*T*ing (WOEST) trial, use of clopidogrel without aspirin was associated with a significant reduction in bleeding complications and no increase in thrombotic events compared to clopidogrel with aspirin in patients undergoing PCI who were receiving oral anticoagulation.[112] Caution is required when using these agents in patients who require an anticoagulant or who are at significantly increased risk for bleeding.[1]

In the case of J.S., owing to a new diagnosis of atrial fibrillation, an assessment of thromboembolic and bleeding risk would be warranted. With a CHA_2DS_2-VASc (Congestive heart failure,

Hypertension, Age ≥75 years [doubled], Diabetes mellitus, prior Stroke or TIA or thromboembolism [doubled], Vascular disease, Age 65 to 74 years, Sex category) score of 5 and a HAS-BLED (*H*ypertension, *A*bnormal renal or liver function, *S*troke, *B*leeding, *L*abile INR, *E*lderly, *D*rugs and alcohol) score of 3, oral anticoagulation would be warranted, but caution should be exercised because of bleeding risk (see Chapter 15, Cardiac Arrhythmias). A DOAC, such as apixaban 5 mg bid, dabigatran 150 mg bid, edoxaban 60 mg/day, or rivaroxaban 20 mg/day, would be preferred. Given the risk of stent-related complications early on, consider discontinuation of aspirin after 30 days. After 12 months, the $P2Y_{12}$ inhibitor can be stopped and replaced with low-dose aspirin 81 mg/day. It would also be reasonable to consider clopidogrel instead of prasugrel in J.S.

Proton-Pump Inhibitors

Case 13-3, Question 8: Should J.S. receive a proton-pump inhibitor (PPI)?

The ACC/AHA/American College of Gastroenterology recommends using a PPI in patients receiving DAPT who have multiple risk factors for gastrointestinal bleeding such as advanced age; concomitant use of warfarin, steroids, or NSAIDs; or *Helicobacter pylori* infection.[113] The ACC expert consensus decision pathway recommends a PPI or histamine H_2 receptor antagonist in patients on two or more antithrombotic agents to minimize gastrointestinal bleeding. Once the patient is on just one antithrombotic agent, it is important to discontinue these agents to minimize long-term risks and complications specifically associated with PPI use.[110] Because omeprazole and esomeprazole are known to inhibit the isoenzyme 2C19, the FDA recommends against the use of these with clopidogrel because of the possible reduced effectiveness of clopidogrel.[1,114]

Case 13-3, Question 9: How would you summarize the long-term therapy needed by J.S. on discharge?

Appropriate discharge medications for J.S. include a β-blocker, ACE inhibitor, aldosterone antagonist, high-intensity statin, SGLT2 inhibitor, aspirin 81 mg/day, $P2Y_{12}$ inhibitor (clopidogrel or ticagrelor), PPI (or histamine H_2 receptor antagonist), and a DOAC. He also should receive a prescription for SL NTG to carry with him for use PRN. Many of these important discharge medications are specified by the Joint Commission as national performance and quality measures for AMI. This specifically includes statin, β-blocker, aspirin, and ACE inhibitor (or ARB) and aldosterone antagonist for LVEF <40% prescribed at discharge.[35] Continuation of the $P2Y_{12}$ inhibitor beyond 1 year may be considered after careful assessment of the patient's ischemic and bleeding risk. His previous hydrochlorothiazide may be discontinued because his hypertension will likely be controlled with the β-blocker, ACE inhibitor, and aldosterone antagonist. His metformin should be continued and an SGLT2 inhibitor added, with close monitoring of blood glucose. Because J.S. will have several new medications, he will need education regarding his medications before discharge to optimize medication adherence.

LIFESTYLE MODIFICATIONS

Case 13-3, Question 10: What types of lifestyle modifications should J.S. be encouraged to pursue to reduce his risk factors?

J.S. must be encouraged to stop smoking; this may be the most important change he can make (see Chapter 91, Tobacco Use and Dependence).[115] For weight management, an initial goal weight loss should be to reduce body weight by ~10% from baseline if BMI

exceeds 25 kg/m^2.[92] Other dietary modifications should be implemented so that J.S. can maintain a hemoglobin A_{1c} <7.0% and achieve a BP goal of <140/90 mm Hg (or possibly lower) because J.S. has diabetes, and a serum LDL <100 mg/dL.[92,116,117,118] (See Chapter 8, Dyslipidemias, Atherosclerosis, and Coronary Heart Disease; Chapter 9, Essential Hypertension; and Chapter 12, Chronic Stable Angina, for further information on antihypertensive and lipid-lowering drugs, as well as diet therapy.)

SUMMARY

Although mortality and incidence rates for ACS appear to be on the decline, ACS still remains a major cause of morbidity and mortality in the United States. The use of PCI has significantly improved the survival of patients with STEMI. The major risk associated with thrombolysis is bleeding, especially intracerebral hemorrhage. Another problem associated with fibrinolytic therapy is reocclusion of the artery that was initially opened. PCI is more effective than is fibrinolytic therapy; however, it is available only in hospitals with experienced invasive cardiologists, thereby limiting its availability to some patients.

Aspirin should be given to all patients with ACS unless there is a contraindication. β-Blockers and statins should be administered as well. $P2Y_{12}$ inhibitors are recommended with aspirin in all patients with ACS with or without stenting. ACE inhibitors, ARBs, and aldosterone antagonists have been shown to be beneficial in patients who have LV dysfunction (LVEF <40%) and are also recommended for secondary prevention. More recently, SGLT2 inhibitors have been shown to convey cardiovascular benefit and may be considered in patients who have diabetes and/or LV dysfunction (LVEF <40%). Nitrates are useful, but care must be taken to maintain an adequate perfusion pressure. Secondary

prevention emphasizing a healthy lifestyle and aggressive lipid lowering are important components to the overall treatment plan.

Heart Failure

Harleen Singh and Joel C. Marrs

CORE PRINCIPLES		CHAPTER CASES
1	Heart failure (HF) is a “clinical syndrome with symptoms and/or signs caused by a structural and/or functional cardiac abnormality and corroborated by elevated natriuretic peptide levels and/or objective evidence of pulmonary or systemic congestion.” This is further classified according to left ventricular ejection fraction.	**Case 14-1 (Question 1)**
2	HF symptoms, including limitations in activity, can be quantified with the use of the New York Heart Association functional classification system and the American College of Cardiology–American Heart Association classification of chronic HF. The cardinal signs and symptoms (eg, peripheral	**Case 14-1 (Questions 2, 3)**

	edema, dyspnea, fatigue) of HF must be evaluated in light of the patient's medical history, physical examination, and results of additional testing.	
3	Coexisting medical conditions that lead to HF (eg, ischemic heart disease, hypertension, atrial fibrillation [AF], diabetes mellitus, sleep apnea) or result from HF (eg, AF, cachexia, depression) may influence the overall prognosis and treatment; therefore, these should be assessed on a routine basis.	**Case 14-1 (Question 4)** **Case 14-5 (Question 3)**
4	Several categories of medications (such as nonsteroidal anti-inflammatory drugs and "glitazones") may exert unfavorable hemodynamic effects and may precipitate HF symptoms in patients with previously compensated HF. In some patients, the occurrence of HF can be attributed to the cardiotoxic effect of a particular medication (cancer chemotherapeutic drugs).	**Case 14-1 (Question 5)**
5	Treatment goals are to improve symptoms, decrease hospitalizations, and prevent premature death in patients. The cornerstone of treatment for heart failure with reduced ejection fraction (HFrEF) is to optimize life-prolonging therapies (eg, angiotensin converting enzyme inhibitors, angiotensin receptor blocking agents, angiotensin receptor–neprilysin inhibitors, β-blockers, aldosterone	**Case 14-1 (Questions 6–22)** **Case 14-2 (Question 1)** **Case 14-3 (Questions 1–9)** **Case 14-4 (Questions 1, 2)**

	antagonists, sodium–glucose cotransporter-2 inhibitors, and promote healthy lifestyle choices (eg, sodium restriction, exercise training). In selected patients, ivabradine can be added for additional heart rate lowering.	
6	Prompt recognition of symptoms and appropriate treatment are critical in the management of acute decompensated HF. The mainstay of therapy in patients with volume overload is an intravenous loop diuretic. Other therapies (eg, inotropic drugs) have failed to show long-term benefits in clinical trials.	**Case 14-5 Questions 1–3)** **Case 14-6 (Questions 1, 2)**
7	To reduce the risk of sudden cardiac death due to ventricular arrythmias an implantable cardioverter-defibrillator or amiodarone should be considered. Cardiac resynchronization therapy can be used in combination to improve symptoms and quality of life in patients with severe HF symptoms.	**Case 14-6 (Questions 3–5)** **Case 14-7 (Questions 1, 2)**
8	There is little clinical trial evidence to guide which treatments are optimal to use in heart failure with normal or preserved left ventricular ejection fraction (HFpEF).	**Case 14-8 (Question 1)**
9	Although controversial, certain patients may respond differently to drug therapy (eg, African American patients, females).	**Case 14-3 (Question 3)** **Case 14-4 (Question 2)**
10	HF is an extremely serious condition	**Case 14-9 (Question**

and requires careful diagnosis, ongoing monitoring, and the implementation of evidence-based therapy. Herbal remedies (eg, hawthorn) have some evidence to support their role in improving symptoms of HF; however, they have no evidence demonstrating improvements in mortality. Herbals can also potentially interact with other heart medications.	1)

INTRODUCTION

The definition, descriptive terminology, diagnostic techniques, and treatment of heart failure (HF) have undergone significant change in the past 20 years. Since 1994, a series of consensus- and evidence-based practice guidelines have been published in an effort to standardize HF management. Guidelines from the Heart Failure Society of America (HFSA),[1] American College of Cardiology (ACC), American Heart Association (AHA),[2] and the European Society of Cardiology[3] (ESC) have been revised over the years and updated to reflect ongoing changes in the management of HF. In March 2021, the HFSA, the Heart Failure Association of the European Society of Cardiology (HFA-ESC), and the Japanese Heart Failure Society (JHFS) released a consensus statement on the Universal Definition and Classification of Heart Failure.[4]

The proposed universal definition describes HF[4] as a “clinical syndrome with symptoms and/or signs caused by a structural and/or functional cardiac abnormality and corroborated by elevated natriuretic peptide (NP) levels and/or objective evidence of pulmonary or systemic congestion.” The intent of this new definition was to standardize HF management. The HF societies recognized that the textbook definition “A clinical syndrome caused by the

inability of the heart to supply blood to meet tissue metabolic requirements" has certain limitations and interpretation of the current definition can be confusing for nonspecialists, patients, and payers.

Furthermore, the HF definition by numerous guidelines differs from the textbook definition and from each other. Some guidelines utilize symptoms (dyspnea, fatigue) or physical findings, whereas others include assessment of hemodynamic, neurohormonal, or circulatory abnormalities to define HF. Unlike other disease states such as cancer, diabetes, chronic obstructive pulmonary disease (COPD), and so on, that have specific standardized criteria for diagnosis, HF diagnosis lacks specificity. Also, there are multiple etiologies associated with HF, thus adding another layer of complexity to diagnose and treat HF in clinical practice. In the past 20 years, despite advances in HF management, optimization of guideline-directed medical therapy (GDMT) continues to be suboptimal as reported by real-world registries, suggesting a lack of ability to standardize care in practice. As the burden of HF continues to increase, the need for a standardized definition that is clinically relevant, globally applicable, and allows for timely implementation of GDMT was deemed necessary.

Congestive heart failure (CHF) is a subset of HF characterized by left ventricular systolic dysfunction (LVSD) and volume excess. However, some patients may lack symptoms of congestion and still have reduced cardiac output (CO) manifesting as fatigue and reduced exercise tolerance. Therefore, the term CHF has been replaced with HF.

The ACC/AHA guidelines and updates 2, 5, and 6 provide a comprehensive review on prevention, diagnosis, risk stratification, and treatment of HF in both outpatient and inpatient settings. The updates emphasize how to implement GDMT, how to overcome barriers to safely titrate medications, and improve adherence to therapy in clinical practice.

Numerous programs and systems have been implemented in an attempt to decrease the cost and length of hospital stay for HF. It is recommended that practitioners look at least annually for the most

recently published guidelines to be aware of the rapidly evolving treatment strategies for HF.

Incidence, Prevalence, and Epidemiology

It is estimated that there are 6.2 million people (1.5%–2% of the population) with HF in the United States, and ~23 million people with HF worldwide. The prevalence of HF continues to increase, with an estimated 46% increase in prevalence by 2030.[5] Every year, 870,000 people have a new diagnosis of HF, and at 40 years of age, 1 in 5 persons has a lifetime risk of developing this syndrome. After age 65, HF incidence approaches 21 per 1000 person-years and is the most common cause of hospitalizations in the elderly population in the United States.

The incidence of HF is greater in males and in the elderly; however, the incidence in Black females is as high as that in White males. In females, coronary artery disease (CAD) and diabetes are considered the strongest risk factors for HF. African Americans present with HF at a younger age compared with White individuals. Risk factors, such as ischemic heart disease, hypertension (HTN), gender, obesity, and diabetes, among others, that predict the incidence of HF as well as its severity have been identified.[5]

In older individuals, the survival after new onset of HF has improved; however, survival benefits are not similar across all demographics, and one in nine deaths has HF mentioned on the death certificate.[5] Evidence from national databases and community-based cohorts indicates that the incidence of HF seems to be stabilizing, if not decreasing, for females, and that the length of survival in patients with HF is increasing. However, the death rate remains high; almost 50% of people diagnosed with HF will die within 5 years. The mortality risk steadily increases each year after the diagnosis of HF. The 6-month mortality rates are no different in patients with preserved versus reduced left ventricular ejection fraction (LVEF).[6] HF costs are currently estimated at $30.7 billion. If

no improvements are made to current treatment outcomes, it is expected to grow to $69.8 billion by the year 2030.

Various risk prediction models have been developed to predict HF outcomes. Given the heterogeneous nature of the HF population (ischemic vs nonischemic, low vs preserved ejection fraction [EF]), and multiple comorbid conditions, the validity of the risk prediction models is not consistent in all populations with HF. Therefore, it is important to identify patients who are at high risk for HF and how various risks factors can predict outcomes.[7] Based on the strength of these associations, prevention measures need to be designed to decrease HF hospitalizations in targeted subpopulations. The 2013 guidelines[2] emphasize that validated multivariable risk scores can be useful to estimate subsequent risk of mortality in ambulatory or hospitalized patients with HF.

Etiology

LOW-OUTPUT VERSUS HIGH-OUTPUT FAILURE

HF has been described as being either *low-output* or *high-output failure,* with a predominance of cases being low-output failure (**Table 14-1**). In both types, the heart cannot provide adequate blood flow (tissue perfusion) to meet the body's metabolic demands, especially during exercise. The hallmark of classic low-output HF is a diminished volume of blood being pumped by a weakened heart in patients who have normal metabolic needs.

Table 14-1
Classification and Etiology of Left Ventricular Dysfunction

Type of Failure	Characteristics	Contributing Factors	Etiology
Low output, systolic dysfunction (dilated cardiomyopathy)[a]	Hypofunctioning left ventricle; enlarged heart (dilated left ventricle); ↑left ventricular end-diastolic volume; EF <40%; ↓stroke volume; ↓CO; S_3 heart sound present	1 ↓Contractility (cardiomyopathy) 2 ↑Afterload (elevated SVR)	1 Coronary ischemia,[b] MI, mitral valve stenosis or regurgitation, alcoholism, viral syndromes, nutritional deficiency, calcium and potassium depletion, drug-induced, idiopathic 2 Hypertension, aortic stenosis, volume overload
Diastolic dysfunction	Normal left ventricular contractility; normal size heart; stiff left ventricle; impaired left ventricular relaxation; impaired left ventricular filling; normal EF; S_4 heart sound	1 Thickened left ventricle (hypertrophic cardiomyopathy) 2 Stiff left ventricle (restrictive cardiomyopathy) 3 ↑Preload	1 Coronary ischemia,[b] MI hypertension, aortic stenosis and regurgitation, pericarditis, enlarged left ventricular septum (hypertrophic cardiomyopathy) 2 Amyloidosis, sarcoidosis 3 Sodium and water retention
High-output failure (uncommon)	Normal or ↑contractility; normal size heart; normal left ventricular end-diastolic volume; normal or ↑EF; normal or increased stroke volume; ↑CO	1 ↑Metabolic and oxygen demands	1 Anemia and hyperthyroidism

CO, cardiac output; EF, ejection fraction; MI, myocardial infarction; SVR, systemic vascular resistance.

[a]Same as congestive heart failure if symptoms also present.

[b]Heart failure caused by coronary artery ischemia or myocardial infarction classified as ischemic etiology. All other types combined and classified as nonischemic.

In high-output failure, the heart is healthy and pumps a normal or an even higher than normal volume of blood. Because of high metabolic demands caused by other underlying medical disorders (eg, hyperthyroidism, anemia), the heart becomes exhausted from the increased workload and eventually cannot keep up with demand. The primary treatment of high-output HF is amelioration of the underlying disease. Unless otherwise stated, this chapter focuses on the treatment of low-output HF.

LEFT VERSUS RIGHT VENTRICULAR DYSFUNCTION

Low-output HF is further divided into left ventricular (LV) and right ventricular dysfunction, or a combination of the two (biventricular failure). Because the left ventricle is the major pumping chamber of the heart, *LV dysfunction* is the most common form of low-output HF and the major target for pharmacologic intervention. Right ventricular dysfunction may coexist with LV HF if the damage is sustained by

both sides of the heart or as a delayed complication of progressive left-sided HF.

Isolated right-sided ventricular dysfunction, which is relatively uncommon, is usually caused by either primary or secondary pulmonary arterial HTN. Under these conditions, elevated pulmonary artery pressure impedes emptying of the right ventricle, thus increasing the workload on the right side of the heart.[8,9] Primary pulmonary arterial HTN is idiopathic, caused by increased resistance of the pulmonary arterial vasculature of unknown etiology. Secondary causes of pulmonary HTN include collagen vascular disorders, sarcoidosis, fibrosis, exposure to high altitude, and drug and chemical exposure. Drug-induced causes include opioid overdoses (especially heroin), 5-hydroxytryptamine-2B (5HT-2B) agonists (eg, dexfenfluramine, fenfluramine, and pergolide), and pulmonary fibrosis caused by intravenous (IV) injection of poorly soluble forms of methylphenidate. Right-sided heart disease that occurs as a result of a pulmonary process is known as *cor pulmonale*.

CLASSIFICATION OF HEART FAILURE ACCORDING TO LEFT VENTRICLE EJECTION FRACTION; ISCHEMIC VERSUS NONISCHEMIC HEART FAILURE

Over the years, the classification of HF has evolved based on emerging evidence. Initially, LV dysfunction was subdivided into systolic and diastolic dysfunction, with mixed disorders also being encountered (see **Table 14-1**). In systolic dysfunction, the stroke volume (SV) (the volume of blood ejected with each contraction; normal, 60–130 mL) and the subsequent CO (SV × heart rate [HR]; normal, 4–7 L/minute) are reduced. In diagnosing HF, a critical marker differentiating systolic from diastolic dysfunction is the LVEF, defined as the percentage of LV end-diastolic volume expelled during each systolic contraction (normal, 60%–70%).

In *systolic dysfunction,* the LVEF is <40%, dropping to <20% in advanced HF. Heart failure with reduced ejection fraction (HFrEF) is a result of factors causing the heart to fail as a pump (decreased

myocardial contractility). The heart dilates as it becomes congested with retained blood, leading to an enlarged hypokinetic left ventricle.

HF caused by coronary ischemia or after myocardial infarction (MI) is classified as *ischemic,* with all other types grouped as *nonischemic*. CAD is a common cause of HF in patients with LVSD. Other causes of LV pump failure include persistent arrhythmias, poststreptococcal rheumatic heart disease, chronic alcoholism (alcoholic cardiomyopathy), viral infections, or unidentified etiology (idiopathic dilated cardiomyopathy). Chronic HTN, as well as cardiac valvular disorders (aortic or mitral stenosis), precipitate systolic HF by increasing resistance to CO (a high afterload state).

In contrast, LV diastolic dysfunction refers to impaired relaxation and increased stiffness of the left ventricle; the EF may or may not be abnormal, and the patient may or may not be symptomatic. Some patients have both systolic and diastolic dysfunction. The term *heart failure with normal or preserved left ventricular ejection fraction* (HFpEF) is used for patients who have symptoms of HF but a normal EF. These patients always have diastolic dysfunction.

Possible causes of diastolic dysfunction include coronary ischemia, chronic uncontrolled HTN, LV wall scarring after an MI, ventricular wall hypertrophy, hypertrophic cardiomyopathy, restrictive cardiomyopathy (amyloidosis and sarcoidosis), and valvular heart disease (aortic stenosis). These factors lead to LV wall stiffness (reduced wall compliance) and inability of the ventricle to relax during diastole, which result in an elevated pressure within the ventricle despite a relatively low volume of blood. In turn, the elevated pressure impedes LV filling during diastole that would normally occur by passive inflow against a low-resistance pressure gradient. Heart size is usually (but not always) normal. It is estimated that 20% to 60% of patients with HF may have normal LVEF and reduced ventricular compliance.[10] Because coronary ischemia, MI, and HTN are contributors to both systolic and diastolic dysfunction, many patients have both systolic and diastolic dysfunction.

The pathology of systolic dysfunction most closely resembles what has historically been called *congestive heart failure*. Tremendous variability exists in the clinical presentation of both systolic and

diastolic dysfunction; however, both disorders can have similar symptoms.[9,11] Most patients exhibit exercise intolerance and shortness of breath (SOB) with either systolic or diastolic dysfunction. Some exhibit significant edema, whereas others may have no edema or symptoms of congestion. It is possible to be asymptomatic in the early stages of HF. For all these reasons, it is best to avoid the abbreviation CHF because not all patients have congestion. CHF has also been used to denote "chronic heart failure." Clinicians are strongly encouraged to obtain an EF measurement in all patients. The diagnosis of HF should be based on a combination of symptoms and signs together with appropriate clinical tests.

Population studies have shown that patients with "systolic HF" also presented with LV diastolic dysfunction compared to those with so-called diastolic HF. Interestingly, LV diastolic dysfunction is present even in the absence of HF. Clinical trials defined inclusion criteria–based HFrEF or HFpEF and HF with "normal" EF. The noninvasive assessment of LV function using echocardiography became the standard of care in HF. The guidelines used a cutoff of 50% to define normal LVEF. However, these EF cutoffs became confusing when LVEF was between 40% and 50%. The 2016 European Society of Cardiology HF Guidelines[12] coined the term *HF with mid-range EF (HFmrEF)*, whereas the 2013 American College of Cardiology/American Heart Association HF Guidelines used "borderline" for LVEF of 40% to 50%, respectively. In clinical practice, things got further complicated when patients presented with improved EF, which often led to discontinuation or step-down of life-prolonging therapy. Thus, to close this gap, a new revised nomenclature based on LVEF was proposed. The rationale for standardizing the EF categories was to encourage clinicians to use life-prolonging therapies of HFrEF (such as sodium–glucose cotransporter-2 [SGLT2] inhibitors) and to highlight the expanded indication for angiotensin receptor–neprilysin inhibitor (ARNI) in EF between 45% and 57% based on new evidence.[63] See **Figure 14-1**.
